COMPREHENSIVE MOLECULAR INSECT SCIENCE

EDITED BY
L.I. GILBERT, K. IATROU AND S.S. GILL

Comprehensive Molecular Insect Science

Seven-Volume Set, Volume 1-7

by Kostas Iatrou, Sarjeet S. Gill

Product Details

- **Hardcover:** 3300 pages
- **Publisher:** Pergamon (December 20, 2004)
- **Language:** English
- **ISBN:** 044451516X
- **Product Dimensions:** 12.0 x 9.5 x 9.9 inches
- **Shipping Weight:** 29.3 pounds.

List Price: $2,650.00

Book Description

The important developments and achievements in modern insect science since the first edition have led to this new revised, expanded and retitled reference work. New chapters in this edition include the ecdysone receptor, lipocalins, bacterial toxins, etc. Each article may also be read independently, as a review of that particular subject.

Comprehensive Molecular Insect Science also covers new technologies that have been developed since 1985. The Index Volume will help researchers to track specific subjects and particular species of insects cited in several volumes.

Available Online in 2005 via ScienceDirect!
' Extensive browse and search across subject, thematic, alphabetical, author and cited author indexes - as applicable to the wor k
' Basic and advanced search functionality within volumes, parts of volumes, or across the whole work
' Build, save and re-run searches as well as combine saved searches
' Internal cross-referencing between articles in the work, plus dynamic linking to journal articles and abstract databases, maki ng navigation flexible and easy
' All articles are available as full text HTML files, and as PDF files that can be viewed, downloaded or printed out in their or iginal print format

The online edition of this title is kept under regular editorial review, and enhanced as warranted to reflect the state of current knowledge. Enhancements may take place as frequently as annually and may consist of new versions of existing articles, new articles, or additional material.

Key Features:

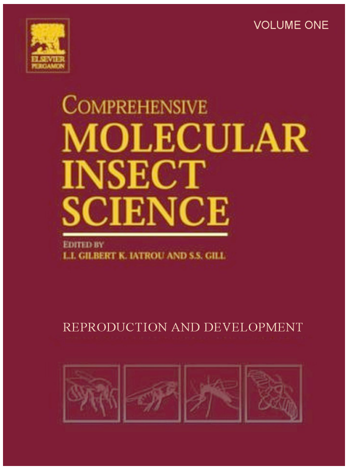
' Revised edition of critically acclaimed **Comprehensive Insect Physiology, Biochemistry and Pharmacology** (1985, Pergamon Press, 13 Volume Set)
' Written by a distinguished international group of contributors
' Well-organized format provides for concise, readable entries, easy searches, and thorough cross-references
' Complete up-to-date coverage of many important topics - essential information for scientists, students, and professionals alik e

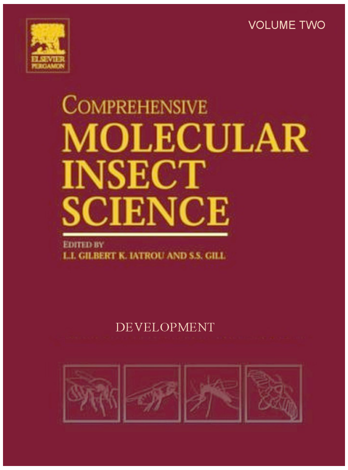
About the Author

Kostas Iatrou is the Director of the "Insect Molecular Genetics and Biotechnology" Research Group at the Institute of Biology, NCSR "Demokritos" and an adjunct Professor of the University of Calgary. He is the former Professor of Biochemistry and Molecular Biology at the Faculty of Medicine, University of Calgary, Canada and Director of the Institute of Biology, National Institute of Scientific Research "Demokritos", Athens Greece. His major research interests are in the areas of insect cell differentiation, development and reproduction. His parallel research activities include the development of insect, insect cell and insect virus-based functional genomics tools and technologies that can be used for a wide variety of biotechnological applications impacting on the fields of insect pest control human disease treatment.

Sarjeet S. Gill is Professor of Cell Biology in the Department of Cell Biology and Neuroscience at the University of California, Riverside, and Entomologist in the Agricultural Experimental Station on the same campus. His research interests are in biochemistry, molecular biology and insect toxicology, with a focus on mechanisms of bacterial and viral pathogenesis, and the role of the midgut and Malpighian tubules in insect homeostasis. Dr. Gill's research also employs the use of whole genome tools to analyze gene function. His research has been continually funded through the NIH and USDA, he continues to serve on national and international committees related to his research interests, and is an elected fellow of the American Association for the Advancement of Science.

Comprehensive Molecular Insect Science





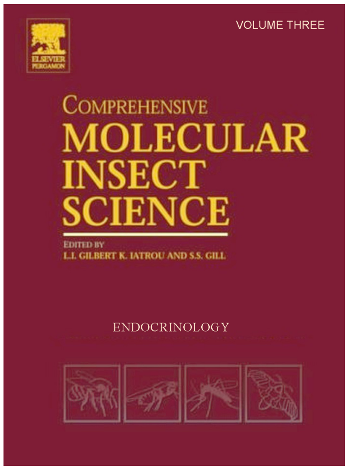


Table of Contents

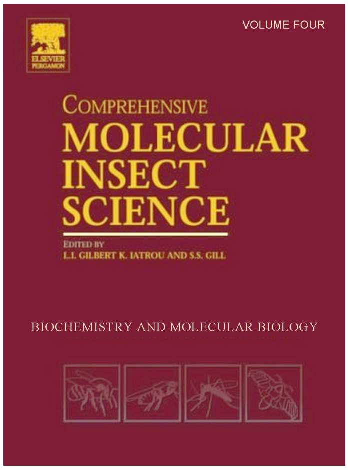
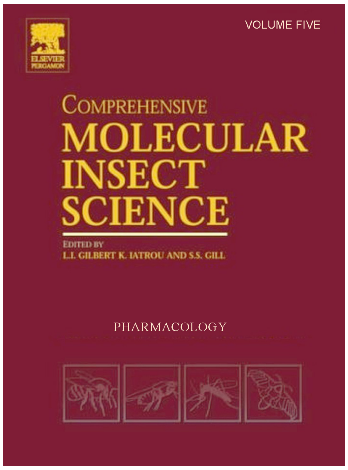
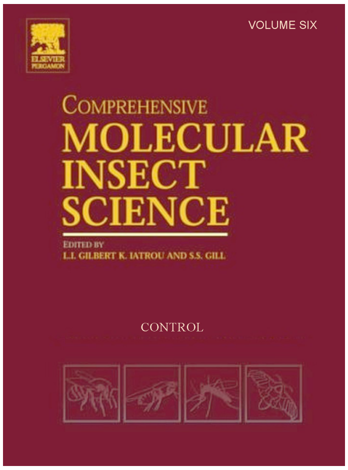
Volume 1: Reproduction and Development



Volume 2: Development



Volume 3: Endocrinology



Volume 4: Biochemistry and Molecular Biology

Volume 5: Pharmacology

Volume 6: Control

Volume 7: Indexes

INTRODUCTION

The first edition of this treatise, entitled *Comprehensive Insect Physiology, Biochemistry, and Pharmacology* and edited by Gerald A. Kerkut (see p. ix for the Dedication to Prof. Kerkut) and Lawrence I. Gilbert, was published in 1985. The preliminary meetings regarding that 13-volume series began in 1980 and it was agreed that there would be 12 volumes "that would provide an up-to-date summary and orientation on the physiology, biochemistry, pharmacology, behavior, and control of insects that would be of value to research workers, teachers, and students." It was felt that the volumes would provide a classical background to the literature, include all the critical basic material, and then emphasize the literature from 1950 to the present day (1984). By mid-1981 most of the chapters were assigned to authors and the project was underway. It was agreed upon that there would be a final Volume 13, an Index volume, that combined the subject, species, and author indexes for all 12 volumes so that all material in those volumes could be located easily. This was a monumental undertaking and the 13 volumes finally appeared in 1985. It received plaudits from reviewers and from researchers around the world. One of us (LG.) was approached by Carrol Williams, an internationally renowned insect physiologist, at an International Congress of Entomology following the publication of the first edition, and Professor Williams noted that he had a choice between purchasing the 13-volume set for his laboratory and buying a new centrifuge. He then stated that he chose the 13-volume series and had never regretted it for a moment. There were more than 50 000 references to the literature in the first edition and more than 10 000 species of insects were referred to, and all of this information was readily available through the thirteenth volume (index). It is of interest that volumes of that original series are still being purchased some 19 years after this series was published.

Over the past 5–6 years, one of us (LG.) was approached many times by colleagues around the world asking when a second edition of this series would be available. There was an obvious need because of the dramatic explosion of knowledge in insect science due to the utilization of molecular biological paradigms and techniques culminating in the elucidation of the *Drosophila* genome (fly database), the *Anopholes* genome, and of course this explosion continues. The use of this technology was really only beginning when the first series was developed and in 2000, 15 years after the publication of the first edition, we and Elsevier agreed that a new edition was necessary. This would be a series in which each chapter would begin by devoting a few pages summarizing the work in a particular research area up to the publication of the first series (1984–1985), and the remainder of the chapter would be a review of the literature from 1985 to 2003. It was agreed upon that each chapter would make full use of data arising from the utilization of molecular technologies if such data were applicable to that particular chapter subject. We chose to fulfill that premise in six volumes plus an index volume and that both a printed version and an electronic version would be available. As is evident, the title of the series has been changed, both to reflect the emphasis on molecular approaches and to alleviate the use of the obviously cumbersome title *Comprehensive Insect Physiology, Biochemistry, Pharmacology, and Molecular Biology,* which would have to be typed every time a researcher refers to a chapter in the series. We do not pretend, however, that this is a truly comprehensive treatise, since critical areas of research, e.g., ecology, evolutionary biology, and behavior, have not been included, but we have chosen to retain the use of the word "Comprehensive" for continuity with the first series.

The reader will note that the number of chapters in the six volumes is certainly well below the number of chapters in the original 12 volumes. The editors made very subjective decisions based on their own experience and knowledge regarding those areas where the most progress had been made over the past 18 years and omitted areas that have not grown significantly. Surely, there are areas of omission that many readers will feel were due to arbitrary decisions or lack of knowledge of the editors. That is bound to be the case although we spent a great deal of time deciding which chapters should be included, but there is little doubt that personal research bias played a role in those decisions. We are certainly confident that these volumes will be of great value to the research community, including postdoctoral investigators and graduate students. The new publishing technology will allow upgrades by the publisher every several years for those areas of research in which significant breakthroughs occur. This, of course, will only occur in the electronic format of the series and it is hoped that at least for the first few upgrades the original authors will take part.

DEDICATION

Professor Gerald Allan Kerkut: 19 August 1927–6 March 2004

Gerald Kerkut began his scientific career in Cambridge, graduating with a first class degree in Natural Sciences (1945–1948). He then elected to remain at Cambridge for his Ph.D. (1948–1951), studying locomotion in starfish under the supervision of Professor Eric Smith in the Department of Zoology. Gerald continued at Cambridge for a further three years (1951–1954) as a junior fellow of his college, Pembroke. During this period, he studied the electrical activity of the gastropod central nervous system, initially selecting slugs but, due to problems of identification, changed to the garden snail, *Helix aspersa*. A species he was to use for nearly 30 years.

In 1954 Gerald moved to the University of Southampton to take up a lectureship in Animal Physiology within the Department of Zoology. Together with Professor Kenneth A. Munday, Gerald established the Department of Physiology and Biochemistry in 1959 and in 1966 was appointed to the second chair of Physiology and Biochemistry. He remained at Southampton throughout his academic life, retiring in 1992, when he was appointed Emeritus Professor. Gerald continued an active association with the University up until his death. He was invited by a number of universities to become chairman of their zoology or physiology departments but he always declined, preferring to remain at Southampton.

Gerald Kerkut had a first class analytical mind, a prodigious capacity for hard work and an extensive knowledge of the scientific literature. He was always ready to challenge accepted dogma and this was very well illustrated in his inaugural lecture entitled "The Missing Pieces," delivered in December 1968 (Kerkut, 1969). In this he reviewed his research on a number of topics, including the variable ionic composition of neurons, the role of the sodium–potassium pump in the maintenance of the resting potential, fast orthodromic and slow antidromic axon transport and amino acids as transmitters. Although much of his earlier research used the snail, Gerald also worked on insects where he was interested in the effect of sudden temperature changes on the nervous system. Using the cockroach leg preparation he observed that a sudden fall in temperature resulted in a transient increase in activity. Intracellular recordings showed that a decrease in temperature resulted in a depolarization of the membrane potential, which was responsible for the transient increase in activity. *Q*-10 values for changes in membrane potential of insect muscle were greater than those predicted from the Nernst equation. This led to his work on electrogenic metabolic pumps, summarized in his book with Barbara York, "*The Electrogenic Sodium Pump*" (Kerkut and York, 1971). Gerald also employed insect preparations for his research on glutamic acid as a transmitter and that certain insect neuron cell bodies possessed overshooting action potentials, for example, the octopamine-containing dorsal unpaired median (DUM) cells.

Having been a great advocate of the use of isolated invertebrate central nervous system preparations, Gerald turned his attention to isolated mammalian preparations in the late 1970s. In particular, he developed the use of the isolated spinal cord in conjunction with Jeff Bagust. Gerald was particularly interested in sensory integration in the dorsal horn of the spinal cord. Although a great protagonist of

isolated preparations, Gerald stressed that observations using isolated preparations must always be related to the living animal.

Gerald Kerkut was also very involved in the publication of scientific data both in terms of books and journals. In the late 1950s he met Robert Maxwell, the founder of Pergamon Press. They immediately formed an excellent rapport, and Maxwell encouraged Gerald to explore his idea of starting a journal in comparative physiology and biochemistry. To cut a long story short, this resulted in the publication of *Comparative Biochemistry and Physiology* with its first number in 1960 and Gerald as co-editor with Bradley T. Scheer. The journal proved a great success and eventually expanded into three sections, namely, Physiology, Biochemistry, and Pharmacology. Gerald continued to edit the journal until 1994. Another of his editing successes was *Progress in Neurobiology*, which he co-edited with John Phillis. Gerald also edited a very successful series of monographs in Zoology, which were published by Pergamon Press. Gerald's interest in publishing work on insects is illustrated by his co-editing with Lawrence Gilbert in 1985 of the first edition of *Comprehensive Insect Physiology, Biochemistry, and Pharmacology.* He was particularly proud of the high standard of scholarship in these volumes.

Gerald was always interested in evolution and with Maxwell's support published "*The Implications of Evolution*" in 1960 (Kerkut, 1960). In this he examined the problem of the evolution and interrelationships of the animal phyla. This was a topic of lasting interest to him and one to which he returned in a mini-review entitled "*Possible Evolutionary Futures for Mankind*" (Kerkut, 1988). In 1988 a Festschrift was organized in Gerald's honor and the proceedings published as a special edition of *Comp. Biochem. Physiol.* Gerald provided the opening chapter, in which he reviewed his research career up to that time (Kerkut, 1989).

Gerald Kerkut enjoyed music, art, and travel. He was an accomplished pianist and had an extensive collection of art books. Up until 6–7 years ago, Gerald traveled widely in the Americas and the Far East. Gerald enjoyed teaching and interacting with undergraduates and postgraduates. Many will retain enduring memories of his humor and concerned interest in their welfare. During his active research period, Gerald trained over 80 postgraduates and their success will provide a lasting legacy to his memory.

Notes on the Subject Index

To save space in the index the following abbreviations have been used:

ETH – ecdysis triggering hormone
GPCRs – G protein-coupled receptors
PBAN – pheromone biosynthesis activating neuropeptide
PDV – polydnaviruses
PTTH – prothoracicotropic hormone
QSAR – qualitative structure-activity relation
RDL – resistance to dieldrin

1.1 Sex Determination and the Development of the Genital Disc

L Sánchez, Centro de Investigaciones Biológicas, Madrid, Spain
N Gorfinkiel and I Guerrero, Universidad Autonoma de Madrid, Spain

1.1.1. Sex Determination in *Drosophila*

1.1.1.1. Introduction and Historical Overview

Perpetuation by sexual reproduction is the rule within the animal kingdom. Males and females are different at the morphological, physiological, and behavioral levels. This sexual dimorphism results from the integration of the sex determination developmental program, which commits the embryo to either the male or the female pathway, and the developmental program which determines the type of cellular structure that will be differentiated in specific regions in the animal.

This review deals with the genetic and molecular bases controlling sex determination and the sexual dimorphic development of the genital disc that gives rise to the terminalia, the most sexual dimorphic structure of the animal. It is focused on *Drosophila* since it is in this organism where a coherent picture about these developmental processes is now emerging. This has become possible thanks to the combination of sophisticated genetic and molecular biology techniques available in this model insect. However, sex determination and development of the genital disc in other insects will be also reviewed here.

In *Drosophila melanogaster*, 2X;2A individuals (X, X chromosome; A, autosomal set) are females and XY;2A individuals (Y, Y chromosome) are males. Since females and males differ in the number of X chromosomes, a process has evolved to eliminate the difference in the doses of the X-linked genes in the two sexes. This process is called dosage compensation (see **Chapter 1.7**). In *D. melanogaster*, the two X chromosomes in females are active and dosage compensation is achieved in males by hypertranscription of the single X chromosome.

A series of results led to the discovery that in *D. melanogaster* sex is determined by the ratio of the X chromosomes to the sets of autosomes. First, XXY and X0 flies are female and male, respectively. This indicates that the Y chromosome plays no role in sex determination. Second, gynandromorphs are sexually mosaic individuals with some portions of the body typically male and others typically female. Such individuals arise from the loss of one X chromosome during the early development of XX flies. The sharp borderline between female and male tissues indicates that each individual cell chooses its sex autonomously, i.e., according to its chromosome constitution. Third, 2X;3A flies are mosaics with male and female structures. Collectively, these results indicate that gender in *D. melanogaster* is not determined by the absolute number of X chromosomes but by the ratio of X chromosomes to the sets of autosomes (X/A ratio signal). Supporting this contention, clones with one X chromosome and one set of autosomes (1X;1A clones) develop into female structures (Santamaría and Gans, 1980; Santamaría, 1983). In 2X;3A mosaic flies, the X/A ratio is at a threshold level between a normal female

and a normal male signal. Some cells interpret this ambiguous signal as female while others interpret it as male.

Based on genotypes with variable X/A ratios, Bridges (1921, 1925) proposed his "balance concept" of sex determination. This hypothesis considers gender as a quantitative character, with continuous variation, under the control of two opposing polygenic signals, whose component factors have a small effect. The female-determining factors are located on the X chromosome and the male-determining factors are located on the autosomes. The opposing action of the two sets of signals would determine the gender of the fly, according to the stoichiometric assumption that two doses of the female-determining factors (two X chromosomes) outweigh the effect of two doses of male-determining factors (two sets of autosomes), leading to female development. However, two doses of male-determining factors (two sets of autosomes) outweigh the effect of one dose of female-determining factors (one X chromosome), leading to male development. In the case of 2X;3A flies, the stoichiometry of the interaction between female- and male-determining factors is such that, within the same fly, in some cells the male development is imposed and in others the female factors prevail leading to female development.

A breakthrough in the understanding of the genetic basis underlying sex determination in *Drosophila* was the work of Cline (1978), who found that *Sex-lethal* (*Sxl*) – a gene whose function depends on the X/A signal – is the key gene controlling both sex determination and dosage compensation processes, in such way that *Sxl* is activated in females (2X;2A) but not in males (X;2A). The function of *Sxl* would determine female sexual development and autosome-like basal transcription of each of the two X chromosomes in 2X;2A flies, whereas the lack of *Sxl* function would cause male sexual development and hypertranscription of the single male X chromosome (dosage compensation).

Gadagkar *et al*. (1982) and Chandra (1985) proposed a model based on noncoding DNA to explain how cells would assess the X/A ratio signal. They proposed the existence of noncoding DNA sequences in the X chromosome (locus π) that would bind a repressor Ω encoded by an autosomal gene ω. Moreover, they incorporated in their model Cline's proposition about *Sxl* as the key gene controlling sex determination (Cline, 1978). In addition, they also incorporate Cline's finding that the maternal product of gene *daughterless* (*da*) is also required for *Sxl* activation (Cline, 1978).

The "noncoding DNA" model consists of the following components. First, the maternal Da product that is stored in the egg; second, the Ω repressor that is encoded by the autosomal gene ω and is activated in the zygote by the maternal Da product; and third, the gene *Sxl* and the locus π, which have affinity for the Ω repressor and RNA polymerase. A central assumption in this model is that the Ω repressor and RNA polymerase compete with each other for binding sites on both the *Sxl* and π loci in such a way that RNA polymerase binds to both loci with a lower affinity than that of the Ω repressor. It was further assumed that *Sxl* has a lower affinity than π for the repressor as well as the polymerase. According to this model, the amount of repressor in male and female embryos would be the same, since both have two copies of the gene ω and both inherit the same amount of maternal Da product. The male embryo has only one X chromosome and therefore only one dose of the low affinity *Sxl* gene and one dose of the high-affinity locus π. The Ω repressor would bind significantly to both sites thus preventing the binding of RNA polymerase to *Sxl*. Consequently, little or no Sxl protein product would be produced. In the female embryo, there are two doses of both *Sxl* and π loci. Most of the Ω repressor will be sequestered by the π sites, so that the *Sxl* loci will be free to bind RNA polymerase. Synthesis of the Sxl product will then take place.

The role of the X/A signal as the primary input for sex determination and dosage compensation could be visualized in two different ways. One possibility is that the X/A signal may be continuously needed during development for the cells to stay in the chosen sexual pathway and maintain the dosage compensation process properly adjusted. Under this hypothesis, X0 clones induced at any time during the development of XX flies would survive and differentiate male structures. Alternatively, the cells could use the X/A signal at a certain time in their development to set up their sex and dosage compensation processes. Under this second hypothesis, X0 clones induced before that time would survive and differentiate male structures, whereas X0 clones induced later would die because their dosage compensation process would be upset.

To answer this question, a clonal analysis strategy was used. Genotypes were constructed that allowed the removal, by mitotic recombination induced by X-irradiation, of one of the two X chromosomes from an XX cell at different times in development. The results demonstrated that the X0 clones induced at around the blastoderm stage survive and differentiate male structures, while clones induced later in development die. However, the X0 clones survive and differentiate male structures if they carry a loss-of-function *Sxl* mutant allele, independent of

the time in development that the clones are induced. These results indicate that the X/A signal irreversibly sets, in a cell-autonomous manner, the state of activity of *Sxl* sometime around the blastoderm stage. Once this is achieved, the X/A signal is no longer needed and the activity of *Sxl* remains fixed (Sánchez and Nöthiger, 1983; Bachiller and Sánchez, 1991).

The capacity of the *Sxl* gene to function as a stable switch is due to a positive autoregulatory function of *Sxl* (Cline, 1984; Bell *et al*., 1991). Genetic evidence for this autoregulatory function came from the discovery of a new class of *Sxl* mutations that affected the sex determination process but still retained enough *Sxl* function to properly control dosage compensation. These *Sxl* mutant alleles showed the property that they do not need the maternal Da product for its expression in the zygote. In addition, they had the capacity of acting in *trans* causing the activation of a wild-type Sxl^+ allele, which otherwise would not be activated because of the absence of maternal Da product (Cline, 1984). The posterior cloning and molecular characterization of *Sxl* demonstrated that this positive autoregulation is due to the requirement of the Sxl protein in the female-specific splicing of its own primary transcript (Bell *et al*., 1991).

The gene *Sxl* controls the expression of two independent sets of regulatory genes (Lucchesi and Skripsky, 1981). The sex determination genes form one set, and mutations in these genes affect sex determination while having no effect on dosage compensation. The other set of genes is formed by the generically called *male-specific lethal* (*msl*) genes; mutations in these genes affect dosage compensation whilst having no effect on sex determination.

This chapter is focused on sex determination in the somatic component of the animal (reviews: Cline and Meyer, 1996; Schütt and Nöthiger, 2000). The germline exhibits sexual dimorphism, as does the somatic tissue. Cells with the 2X;2A chromosomal constitution will follow the oogenic pathway, while XY;2A cells will develop into sperm. Sex determination in the germline will not be reviewed here, and the interested reader is referred to the reviews of Cline and Meyer (1996) and Oliver (2002). Finally, Lucchesi reviews the dosage compensation process elsewhere in this Encyclopedia (see **Chapter 1.7**).

1.1.1.2. The X/A Signal and the Activation of Gene *Sex-lethal*

1.1.1.2.1. Genetic basis of the X/A signal The identification of a set of genes involved in the initial step of *Sxl* activation indicates that a conventional genetic system is at the basis of the X/A signal. The isolation of X-linked genes involved in the formation of the X/A signal was approached by selection of sex-specific lethal mutations. This selection was based on the prediction that any relevant X-linked genes should function as numerator elements of the X/A signal. A numerator element should display several properties:

1. Reduction of its zygotic doses should specifically be lethal to 2X;2A flies (females) as a consequence of a failure to activate *Sxl*, which causes a hypertranscription of the two X chromosomes. This female-specific lethality should be suppressed by Sxl^M mutations. These are constitutive mutations that express female *Sxl* function independently of the X/A signal (Cline, 1978).
2. Increase of its zygotic doses should specifically be lethal to X;2A flies (males), because *Sxl* is inappropriately activated, leading to an alteration of dosage compensation. This male-specific lethality should be suppressed by loss-of-function *Sxl* mutations.
3. The activation of *Sxl* requires the maternal Da product (Cline, 1978). Therefore, mutations and any X-linked numerator of the X/A signal and a lower amount of maternal Da product are expected to display female-specific lethal synergistic interaction. Such interaction is also expected between mutations in different X-linked numerator genes of the X/A signal. In both cases, female lethality should be suppressed by Sxl^M mutations.
4. A variation of the zygotic doses of X-linked numerator genes should alter the sexual phenotype of triploid intersex (2X;3A) flies. An increase should feminize, whereas a reduction should masculinize these individuals.

The expected properties for an autosomal denominator gene of the X/A signal are the opposite of those expected for an X-linked numerator gene.

Genetic analyses have identified a set of zygotic and maternal genes that form the X/A signal. They fall into three classes. First, the X-linked numerator genes *scute* (*sc*, also called *sisterless-b, sis-b*) (Torres and Sánchez, 1989; Parkhurst *et al*., 1990; Erickson and Cline, 1991; Torres and Sánchez, 1991), *sisterless-a* (*sis-a*) (Cline, 1986), *unpaired* (*upd*, also called *sisterless-c, sis-c*) (Jinks *et al*., 2000; Sefton *et al*., 2000), and *runt* (*run*) (Duffy and Gergen, 1991; Torres and Sánchez, 1992). Second, the gene *deadpan* (*dpn*), the only autosomal denominator gene of the X/A signal that has been found so far (Younger-Shepherd *et al*., 1992). Finally, the maternal effect genes are *daughterless* (*da*) (Cline, 1978), *hermaphrodite* (*her*) (Pultz and

Baker, 1995), *extramacrochaetae (emc)* (Younger-Shepherd *et al*., 1992) and a gene(s) located in chromosomal region 7D10;7F12 of the chromosome (Sánchez *et al*., 1994).

Not all of the genes involved in early *Sxl* activation play the same role. Among the X-linked numerator genes required for *Sxl* activation, only the *sc* and *sis-a* genes fulfil all criteria for numerator elements of the X/A signal. The autosomal gene *dpn* is the single known denominator element. The X-linked genes *run* and *upd* also participate in the X/A signal, yet they do not play the predominant role played by *sc* and *sis-a*. Thus:

1. Simultaneous duplications of *run* and *sc* show very low *Sxl*-dependent male-specific lethality (Torres and Sánchez, 1992) compared with the lethal effect produced by *sis-a* and *sc* duplications (Cline, 1988; Torres and Sánchez, 1989).
2. The gene *run* is only expressed in the trunk region of the embryo, whereas *Sxl* is activated in every cell of the embryo (Duffy and Gergen, 1991).
3. The majority of triploid intersexes heterozygous for *run* show normal male terminalia though some of them show a mixture of male and female structures (Duffy and Gergen, 1991; Torres and Sánchez, 1992). In contrast, all triploid intersexes heterozygous for *sc*, for example, show completely normal male terminalia (Torres and Sánchez, 1992). In the case of triploid intersexes heterozygous for *sis-a*, the degree of masculinization is almost complete (Cline, 1986). The terminalia are produced by the genital disc, and this is the most sexual dimorphic region of the fly (see below).
4. While mutations in *sis-a* and *sc* strongly down-regulate Sxl_{Pe}*::lacZ* expression, removal of *upd* activity or its downstream components has a significantly weaker effect, and residual Sxl_{Pe}*::lacZ* expression is still seen in most mutant female embryos (Jinks *et al*., 2000; Sefton *et al*., 2000).
5. The effect of upd^+ transgenes is comparable to that of a chromosomal duplication of upd^+, but is smaller than that seen for extra doses of $sis\text{-}a^+$ or sc^+. Eliminating *upd* activity reduces expression of Sxl_{Pe} but to a lesser extent than eliminating *sis-a* or *sc* (Sefton *et al*., 2000).
6. The female-specific lethal synergistic effect between *run* and a deficiency of *upd* is weaker than the one between *run* and either *sc* or *sis-a*, or that between *upd* and either *sc* or *sis-a* (Sánchez *et al*., 1994, 1998).
7. Males doubly duplicated for a chromosomal region carrying *upd* and either *sc* or *sis-a* are as viable as their brothers carrying only one of the duplications. This means that there is no male-specific lethal synergism between duplications at *upd* and either *sc* or *sis-a* (Sánchez *et al*., 1994).

1.1.1.2.2. Molecular nature of the X/A signal The X/A signal acts on the early *Sxl* promoter and controls *Sxl* expression at the transcription level (Torres and Sánchez, 1991; Keyes *et al*., 1992). By definition, the X/A signal is strictly zygotic and the numerator X-linked products play the key role in forming this signal since the autosomal and maternal products are equally present in the male and female zygotes. Concerning the molecular nature of the X/A signal, only those products are considered for which a clear role has been found.

The Sc (Villares and Cabrera, 1987; Murre *et al*., 1989), Da (Cronmiller *et al*., 1988; Murre *et al*., 1989), and Dpn (Bier *et al*., 1992) proteins contain a basic helix–loop–helix domain (bHLH). The HLH domain allows these proteins to form homodimers or heterodimers, while the basic domain is required for their binding to specific DNA sequences (Murre *et al*., 1989). Emc also belongs to the HLH family but is devoid of a basic domain (Ellis *et al*., 1990; Garrell and Modolell, 1990). SisA is a basic leucine-zipper (bZIP) protein (Erickson and Cline, 1993). Members of the bHLH and bZIP protein families are usually involved in transcriptional regulation (review: Massari and Murre, 2000).

In vitro methods and yeast two-hybrid assays have allowed the analyses of protein–protein interactions. Experimental evidence supports the formation of the following homo- and heterodimers: Sc–Da (Cabrera and Alonso, 1991; Van Doren *et al*., 1991; Deshpande *et al*., 1995; Liu and Belote, 1995); SisA–Da (Liu and Belote, 1995); SisA–Dpn (Liu and Belote, 1995); Dpn–Dpn (Winston *et al*., 1999); Emc–Sc and Emc–Da (Van Doren *et al*., 1991). No interaction has been observed between Sc and Dpn (Deshpande *et al*., 1995; Liu and Belote, 1995) or between Sc and SisA (Liu and Belote, 1995). Nothing is known about the formation of higher-order multimers.

1.1.1.2.3. Role of the products that form the X/A signal The molecular characterization of the X/A signal components has clarified how they act on the early *Sxl* promoter (see **Figure 1**). The Sc and maternal Da products form complexes that induce early *Sxl* transcription by binding to a set of regulatory sites called E-boxes (Massari and Murre, 2000) within the early *Sxl* promoter (Estes *et al*., 1995; Hoshijima *et al*., 1995; Yang *et al*., 2001). The Emc protein forms heterodimer complexes

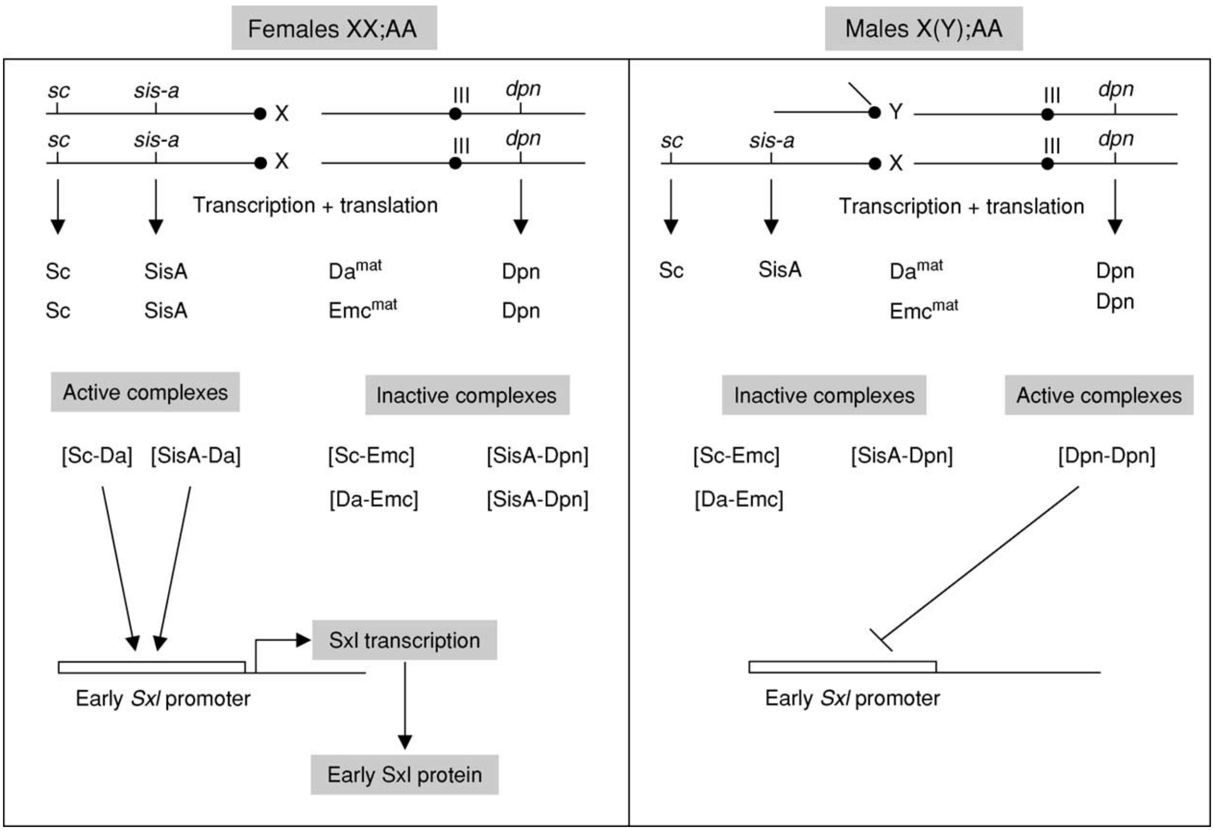

Figure 1 Molecular basis of the X/A signal. The signal represents the ratio between activator and repressor complexes of the early *Sxl* promoter. For simplicity, it is assumed that in females (XX;AA), activators but not repressors are produced, whereas in males (X;AA), repressors but nor activators are formed, so that *Sxl* is only activated in females. Also, for the sake of clarity, representatives of each of the three classes of genes are chosen – X-linked zygotic, autosomal zygotic, and maternal genes – involved in early *Sxl* activation. X, X chromosome; III, third autosome; Y, Y chromosome. See text for explanation.

with either Sc or Da that are unable to bind to DNA (Davis *et al.*, 1990; Voronova and Baltimore, 1990). Therefore, Emc prevents the formation of active Sc–Da complexes.

The SisA protein is required for efficient induction of early *Sxl* transcription (Erickson and Cline, 1991; Estes *et al.*, 1995) although specific binding sites for this protein on the early *Sxl* promoter have yet to be determined. Since the formation of SisA–Da (Liu and Belote, 1995) and SisA–Dpn (Liu and Belote, 1995) complexes has been reported, it is possible that SisA exerts a dual function: on one hand, it forms SisA–Da complexes that activate *Sxl*, and on the other, it sequesters Dpn through the formation of inactive SisA–Dpn complexes. Consequently, it lowers the amount of Dpn that remains free and capable of forming Dpn–Dpn dimers, which repress *Sxl* transcription by binding to a pair of adjacent regulatory sites in the early *Sxl* promoter (Estes *et al.*, 1995; Hoshijima *et al.*, 1995).

1.1.1.2.4. The organization of the early *Sxl* promoter The molecular organization of the early *Sxl* promoter has been determined (Estes *et al.*, 1995; Hoshijima *et al.*, 1995; Yang *et al.*, 2001). It has been shown that a fragment of 1400 bp upstream of the early *Sxl* transcription initiation site contains all the *cis*-acting sequences required for the control of early *Sxl* expression by the X/A signal. Deletion experiments suggest that the upstream distal region (−1.4 to −0.8 kbp) is not essential for sex specificity. In contrast, the proximal region (−390 bp to the transcription initiation site) is necessary and sufficient for transcriptional induction in presence of sufficient amounts of activators. The ostensible function of the distal region is to enhance transcription once it has been initiated by the proximal region; control of early *Sxl* transcription is mainly exerted through the proximal region (Yang *et al.*, 2001).

Binding sites controlled by the repressor have been termed D-boxes. Two D-boxes that bind Dpn dimers lie upstream and close to the transcription initiation site (Hoshijima *et al.*, 1995; Yang *et al.*, 2001). Due to their location close to the transcription start site, binding of the D-boxes is very

likely to inhibit the formation of the transcription machinery.

1.1.1.2.5. The action of the X/A signal on the early *Sxl* promoter The X/A ratio is primarily transduced by the relative amount of positive and negative regulators of *Sxl* (Parkhurst *et al*., 1990; Parkhurst and Ish-Horowicz, 1992). Although early Sxl protein has not been detected in males, suggesting that *Sxl* remains silent in males, it is still possible that *Sxl* transcription occurs in both sexes, but much more efficiently in females (activators outweigh repressors) than in males (repressors outweigh activators). As a result, early Sxl protein is abundantly produced in females whereas it remains undetectable in males.

To explain in molecular terms how the X/A signal could exert its function, for simplicity it is considered that the X/A signal is such that, in females, activators but not repressors are formed whereas in males (X;2A), repressors but not activators are produced, so that early *Sxl* transcription occurs in females, whereas in males this gene remains silent (**Figure 1**). Since the interactions between some of the positive and negative regulators of *Sxl* have been shown, their relative abundance is regulated by a titration mechanism, where the existence of sequestering complexes like Sc–Emc and Da–Emc lowers the availability of free Sc and Da proteins for assembly into active complexes. Alternatively, the formation of SisA–Dpn would lower the amount of free Dpn and the formation of Dpn–Dpn repressors. Because the autosomal zygotic Dpn and the maternal Da and Emc are present in equal amounts in the two sexes, they have no discriminative power in sex determination. The sole difference between males (X;2A) and females (XX;2A) is the number of X chromosomes and, thus, the dosage of the X-linked gene products Sc and SisA. In females, the two doses of *sc* and *sis-a* produce sufficient Sc and SisA products to form Sc–Da and SisA–Da activator complexes, whereas negative Dpn–Dpn complexes are not formed due to the sequestration of Dpn by SisA into inactive SisA–Dpn complexes. Consequently *Sxl* is activated (**Figure 1**). In males, the amount of Sc and SisA products is half of that found in females. Emc sequesters Sc and Da, thus preventing formation of activator complexes. In addition, no SisA is available to sequester Dpn, so that the negative Dpn–Dpn complex is formed that prevents activation of *Sxl*.

As mentioned above, other genes are also known to be required for early activation of *Sxl*:

1. Experimental evidence supports the idea that Run activates *Sxl* transcription by direct interaction with the early *Sxl* promoter. First, Run-binding sites have been identified in the early *Sxl* promoter. Second, a mutant Run protein that cannot bind DNA fails to activate the early *Sxl* promoter. Finally, a modified Run protein containing a heterologous transcription activation domain activates rather than represses the early *Sxl* promoter, indicating that Run does not activate *Sxl* indirectly by repressing a *Sxl*-repressor. Nevertheless, it is not possible to exclude the possibility that the binding of Run to the early *Sxl* promoter interferes with the binding of a *Sxl* repressor (Kramer *et al*., 1999).
2. Both Upd and downstream components – the JAK kinase and the signal transducer and activator of transcription (STAT) – are needed for proper early activation of *Sxl* (Jinks *et al*., 2000; Sefton *et al*., 2000). Interestingly, the X/A signal acts cell-autonomously: the sexual pathway chosen by each cell depends on the cell's chromosome constitution (X/A ratio). This is clearly observed in gynandromorphs (mosaic individuals with portions of the body typically male and others typically female) and in clones where the X/A ratio of the cells has been changed (see above). The question arises as to the function of the JAK/STAT signaling pathway (a noncell-autonomous component) in a cell-autonomous decision process. It has been hypothesized that JAK/STAT signaling between adjacent cells may constitute a mechanism for stochastic compensation of differences in the activation of the early *Sxl* promoter by the X/A signal (Jinks *et al*., 2000). Indeed, gene transcription is a process of an intrinsically probabilistic nature (Zlokarnik *et al*., 1998; Fiering *et al*., 2000; Hume, 2000).
3. The maternal Her product is also necessary for early *Sxl* activation (Pultz and Baker, 1995), although it is not known whether specific binding sites for this protein exist in the early *Sxl* promoter or whether the protein forms complexes with any of the other positive regulators of *Sxl*.

1.1.1.2.6. Developmental meaning of the X/A signal The gene *Sxl* produces two temporally-distinct sets of transcripts corresponding to the function of its two promoters (**Figure 2**). The early set is produced as a response to the X/A signal, which controls *Sxl* expression at the level of transcription. The early promoter functions only around the blastoderm stage, when the X/A signal is formed. Later on, the late promoter starts functioning at the same level in both sexes and remains active throughout development and during adult life in both males and

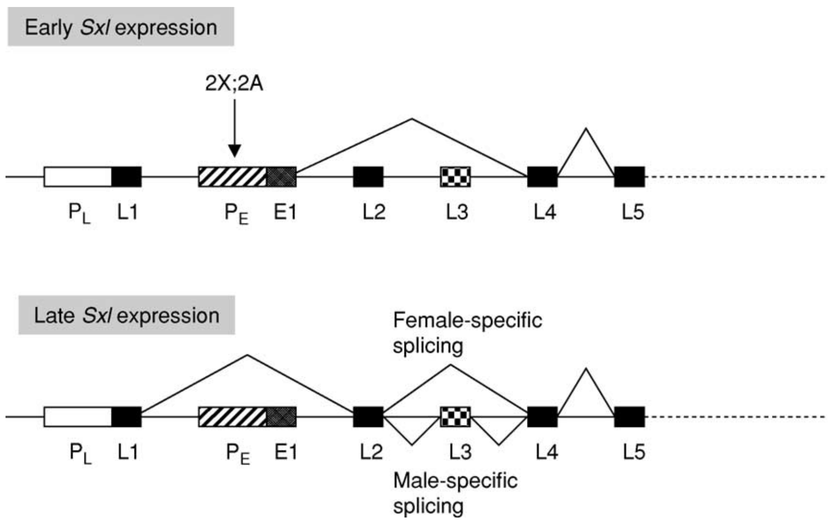

Figure 2 Scheme showing the two expression phases of *Sxl* related to its two promoters. P_L and P_E indicate the late and early promoters. E1 and L1–L5 indicate exons. The boxes and the thin lines represent exons (E1 and L1–L5) and introns, respectively. There are more exons (dotted line) that are included in the early and late *Sxl* mRNAs but these are not involved in the sex-specific and temporally specific splicing regulation of *Sxl* primary transcripts. Note that the early *Sxl* pre-mRNA follows a unique splicing pathway, whereas the late *Sxl* pre-mRNA follows two alternative splicing pathways.

females. In this case, the control of *Sxl* expression occurs by sex-specific splicing of its primary transcript. Male and female processed transcripts differ by the inclusion or exclusion of a male-specific exon (exon L3), which introduces a stop codon in the open reading frame, giving rise to a truncated, nonfunctional Sxl protein. In females, this exon is spliced out and normal, functional Sxl protein is produced (Bell *et al*., 1988; Bopp *et al*., 1991). Female-specific splicing of late *Sxl* pre-mRNA requires the presence of the functional Sxl product, and this constitutes the *Sxl* autoregulatory function (Bell *et al*., 1991).

The early and late *Sxl* transcripts are distinct not only because of the different promoters used for their generation but, also, because of the different splicing pathways they follow (**Figure 2**). The early *Sxl* primary transcripts follow a fixed splicing pattern, where exon L2 and the male-specific exon L3 are excluded, and with the early specific exon E1 being directly spliced to exon L4. Exon L4 and the exons downstream from it are present in both early and late *Sxl* mRNAs. Splicing of the early *Sxl* primary transcript does not require the presence of the Sxl protein (Horabin and Schedl, 1996).

The developmental meaning of the X/A signal is related to the existence of the two *Sxl* gene promoters. In females, early Sxl protein is abundantly produced, because the X/A signal (activators prevail over repressors) efficiently activates the early *Sxl* promoter (**Figure 3**). After the blastoderm stage, when the late *Sxl* promoter begins to function, the abundant early Sxl protein directs the first *Sxl* pre-mRNA to the female-specific splicing pathway that gives rise to late functional Sxl protein, which subsequently ensures that the female-specific splicing state of *Sxl* is set up. In males, early Sxl protein is scarcely produced because the X/A signal (repressors prevail over activators) does not activate efficiently the early *Sxl* promoter. Consequently, when the late *Sxl* promoter starts functioning in males, the first *Sxl* pre-mRNA follows the male-specific splicing pathway that produces a truncated, nonfunctional Sxl protein. The result is the establishment of the male-splicing state of *Sxl*.

Thus, the developmental meaning of the X/A signal is to provide the cells, at the beginning of development, with a sufficient quantity of early Sxl protein, which ascertains the female-splicing control of late *Sxl* pre-mRNA producing functional Sxl protein.

1.1.1.3. The Sex Determination Genetic Cascade

The epistatic relationships between the sex determination genes revealed that a hierarchical interaction exists among these genes (Baker and Ridge, 1980). The characterization of these genes showed that their expression during development is controlled by sex-specific splicing of their primary transcripts: the product of a gene controls the sex-specific splicing of the pre-mRNA of the downstream gene in the genetic cascade.

Sxl is at the top of this cascade: its product controls the splicing of its own pre-mRNA and the splicing of the pre-mRNA from the downstream gene *transformer* (*tra*). The Tra product and the

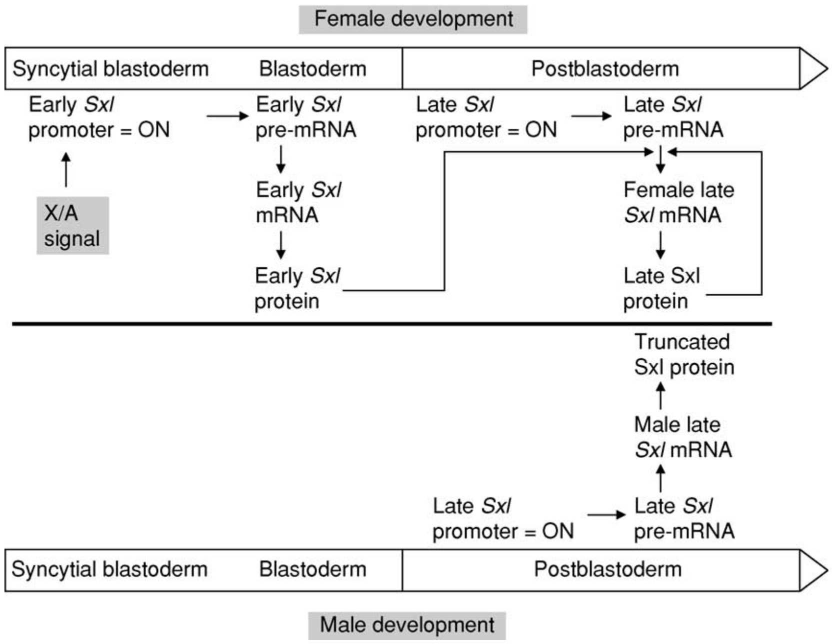

Figure 3 Scheme showing the developmental meaning of the X/A signal. For simplicity, it is assumed that the X/A signal is only produced in females. See text for details.

product of the constitutive gene *transformer-2* (*tra-2*) control the sex-specific splicing of pre-mRNA from gene *doublesex* (*dsx*), which is transcribed in both sexes but gives rise to two different proteins, Dsx^F and Dsx^M, in females and males, respectively. The genes *intersex* (*ix*) and *her* are expressed in both sexes and in females, their products assist Dsx^F to activate female terminal differentiation and to repress male terminal differentiation, whereas Her helps Dsx^M to activate male terminal differentiation and to repress female terminal differentiation (**Figure 4**).

The gene *dsx* is the last gene in the genetic cascade that controls the development of sexual somatic characters, yet there are exceptions. These concern the sex-specific characteristics of the central nervous system and the neuronal induction of a male-specific abdominal muscle, which depend on the function of *tra* and not *dsx* through the genes *fruitless* and *dissatisfaction* (**Figure 4**). The gene *takeout*, which is expressed in the fat body tissue, is closely associated with the adult brain function and is involved in male courtship behavior (Dauwalder *et al.*, 2002). The determination of sexual behavior will not be reviewed here. The interested reader is referred to other reviews on the subject (Yamamoto *et al.*, 1998; O'Kane and Asztalos, 1999; Billeter *et al.*, 2002).

1.1.1.3.1. Control of *Sxl* expression by sex-specific splicing of its primary transcript The mechanism by which Sxl precisely controls the skipping of its male-specific exon L3 is not totally understood. In contrast to most examples of exon-skipping events described in the literature, Sxl promotes a 100% switch between the two alternatively spliced forms of its own pre-mRNA, suggesting the existence of a complex mechanism of regulation. The role of the Sxl protein in the splicing of its own pre-mRNA is highlighted in brief. More extensive details have been reviewed in Penalva and Sánchez (2003).

The *Sxl* gene encodes one of the best-characterized members of the family of RNA-binding proteins. It has two segments, located in tandem in the central portion, with similarity to the RNA-binding domain sequences (RBD) or RNA recognition motifs (RRM). The amino terminus of Sxl is very rich in glycine. It has been shown that this domain is implicated in protein–protein interactions (Sxl multimerization) and absolutely required for proper control of *Sxl* RNA alternative splicing (Wang and Manley, 1997; Waterbury *et al.*, 2000; Lallena *et al.*, 2002). Deletions of the N- and C-termini does not interfere with the ability of the Sxl RBDs to properly bind *in vitro* to their target sequences, while both RNA-binding domains are required for site-specific RNA binding (Wang and Bell, 1994; Kanaar *et al.*, 1995; Sakashita and Sakamoto, 1996; Samuels *et al.*, 1998).

The Sxl-binding sequence consists of long stretches of poly(U) interrupted by two to four guanosines (Sosnowski *et al.*, 1989; Inoue *et al.*, 1990;

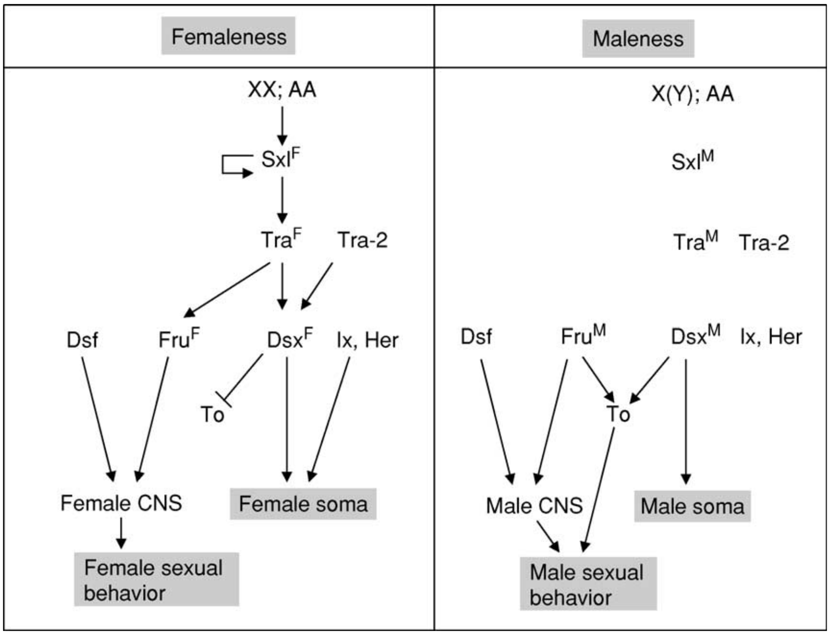

Figure 4 Sex determination gene network. Sxl^F and Sxl^M stand for functional female and nonfunctional truncated male Sxl protein, respectively. Tra^F and Tra^M stand for functional female and nonfunctional truncated male Tra protein, respectively. Dsx^F and Dsx^M stand for functional Dsx protein in females and males, respectively. Fru^F and Fru^M stand for functional Fru protein in females and males, respectively. Dsf is *dissatisfaction*. To is *takeout*. In the absence of the X/A signal in males, the default state corresponds to the production of Sxl^M, Tra^M, and Dsx^M proteins. Ix and Her proteins are produced in both sexes. CNS, central nervous system. For description of the genes and their regulation see text.

Sakamoto *et al.*, 1992; Horabin and Schedl, 1993a, 1993b; Sakashita and Sakamoto, 1994; Samuels *et al.*, 1994; Singh *et al.*, 1995; Wang and Manley, 1997). It has been observed that Sxl binds to RNAs containing two or more poly(U) sequences in a cooperative manner (Wang and Bell, 1994; Kanaar *et al.*, 1995). Different models have been proposed for the molecular mechanism underlying the role of Sxl protein in controlling the female-specific splicing of its own pre-mRNA (Sakamoto *et al.*, 1992; Horabin and Schedl, 1993a, 1993b; Wang and Bell, 1994; Wang and Manley, 1997; Waterbury *et al.*, 2000; Penalva *et al.*, 2001; Lallena *et al.*, 2002; Nagengast *et al.*, 2003). Nevertheless, there is a common aspect to all of them, namely, the fact that the Sxl protein participates in the skipping of the male-specific exon L3 (female-specific splicing of *Sxl* pre-mRNA) through binding to multiple U-rich sequences placed in introns 2 and 3, surrounding the male-specific exon L3 (**Figure 5**). Multiple poly(U) sequences are also present in the adjacent introns of the male-specific exon L3 of the *Sxl* genes of *D. virilis* (Bopp *et al.*, 1996) and *D. subobscura* (Penalva *et al.*, 1996).

The female-specific splicing of late *Sxl* pre-mRNA requires, in addition to the Sxl protein, the function of other genes, such as *sans fille* (*snf*) (Albrecht and Salz, 1993; Flickinger and Salz, 1994; Salz and Flickinger, 1996; Samuels *et al.*, 1998), *female-lethal-2-d* (*fl(2)d*) (Granadino *et al.*, 1990, 1992; Penalva *et al.*, 2000; Ortega *et al.*, 2003), and *virilizer* (*vir*) (Hilfiker and Nöthiger, 1991; Hilfiker *et al.*, 1995; Niessen *et al.*, 2001). These genes, however, do not play any role in the splicing pattern of early *Sxl* transcripts (Horabin and Schedl, 1996).

1.1.1.3.2. *Sxl* protein as its own translation repressor *Sxl* gives rise to a variety of transcripts, some of them stage- and tissue-specific (Salz *et al.*, 1989; Samuels *et al.*, 1991; Keyes *et al.*, 1992; Penalva *et al.*, 1996). The *Sxl* mRNAs also contain several Sxl-binding sites at the 3′ unstranslated region (UTR). It has been shown that the association of Sxl protein with the 3′ UTR of *Sxl* mRNA significantly decreases Sxl protein expression (Yanowitz *et al.*, 1999). Transcripts having a short 3′ UTR are more abundant in the germline and during the early stages of embryogenesis (5–8 h postfertilization) (Salz *et al.*, 1989). In later stages of development and during adult life, the most abundant transcripts have a long 3′ UTR (up to 3600 nt) containing several Sxl binding sites (13 in the largest transcript) (Samuels *et al.*, 1991).

It was speculated that the negative autoregulatory loop of *Sxl* might play an important homeostatic role and that the presence of short transcripts at

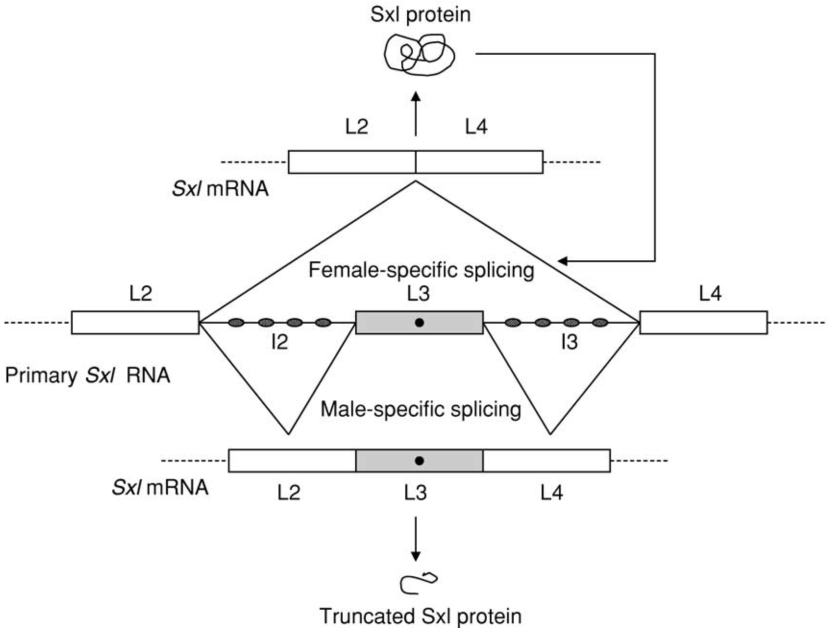

Figure 5 Sex-specific splicing of late *Sxl* pre-mRNA (autoregulatory *Sxl* function throughout development and adult life). Only the key exons (L2–L4) and introns (I2–I3) of the pre-mRNA are shown. The dot inside exon L3 represents translation stop codons. The hatched ellipsoids in introns I2 and I3 represent the sequences bound by the Sxl protein. Exons and introns are not drawn to scale and the numbers and distribution of Sxl-binding sequences are also not drawn to scale.

early stages of development allows a substantial amount of Sxl protein to be produced and a positive autoregulatory loop to be established via splicing. Once accumulation of the Sxl protein is no longer required, short mRNAs are substituted for larger ones whose expression can be repressed by Sxl. The balance between the negative and the positive posttranscriptional controls keeps the concentration of Sxl at levels that do not interfere with other cellular functions but are sufficient for regulation of *Sxl* splicing and splicing of its target genes (Yanowitz *et al*., 1999). Indeed, it has been shown that high levels of Sxl protein have toxic consequences for the cells (Meise *et al*., 1998; Saccone *et al*., 1998).

1.1.1.3.3. The role of transformer in sex determination The *tra* gene is transcribed in both sexes, but its RNA follows alternative splicing pathways (**Figure 6**). Intron 1 of *tra* has two alternative 3′ splice sites. A non-sex-specific transcript is generated when the proximal 3′ splice site is used. Use of this splice site introduces a stop codon in the open reading frame, leading to the production of a truncated, nonfunctional peptide. In females, approximately half of the *tra* pre-mRNA is spliced differently due to the intervention of the Sxl protein. In this case, the distal 3′ splice site is used. As a result, the stretch containing the termination codon is not included in the mature transcript and synthesis of full length Tra protein occurs (Boggs *et al*., 1987; Belote *et al*., 1989) (**Figure 6**).

It has been determined that Sxl regulates female-specific *tra* pre-mRNA splicing by a blockage mechanism rather than by enhancing the use of the female specific 3′ splice site (distal 3′ss). There is a Sxl binding site at the polypyrimidine tract of the non-sex-specific splice site (proximal 3′ss) (Sosnowski *et al*., 1989; Inoue *et al*., 1990). This region is also the binding site for the U2 auxiliary factor (U2AF), an essential splicing factor important for the recognition of the 3′ splice site. U2AF but not Sxl binds also to the polypyrimidine tract associated with the female-specific 3′ splice site, but with 100 times less affinity (Valcárcel *et al*., 1993). Chimeric proteins containing the effector domain of U2AF fused to the complete RNA binding domain of Sxl inhibit rather than promote splicing to the non-sex-specific 3′ splice site. This suggests that Sxl and U2AF compete for binding to the polypyrimidine tract associated with the non-sex-specific 3′ splice site. Binding of Sxl to this sequence displaces U2AF, diverting it to the low affinity distal polypyrimidine tract and promoting the usage of the female-specific 3′ splice site (Valcárcel *et al*., 1993; Granadino *et al*., 1997) (**Figure 6**).

The chimeric U2AF–Sxl protein, however, does not disrupt *Sxl* pre-mRNA splicing regulation, in

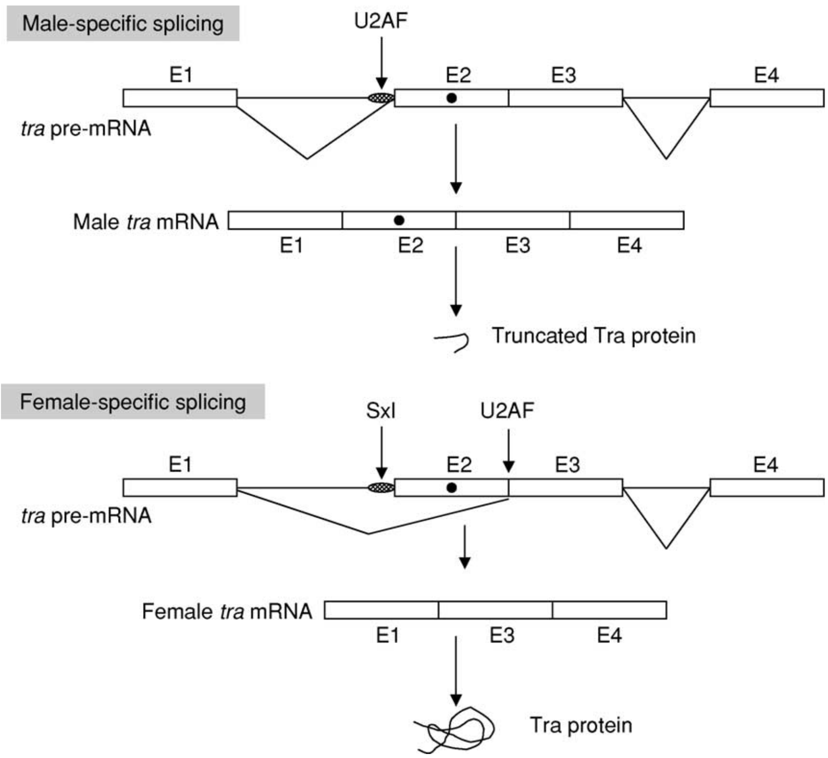

Figure 6 Sex-specific splicing of *tra* pre-mRNA. Boxes and thin lines represent exons (E1–E4) and introns, respectively. The dot inside exon E2 represents translation stop codons. The hatched ellipsoid in front of exon E2 represents the sequence to which both Sxl and U2AF proteins bind.

contrast to what occurs with *tra* splicing (Granadino *et al.*, 1997). These data suggest that Sxl controls *tra* and *Sxl* pre-mRNA alternative splicing by different mechanisms. Notwithstanding, there is controversy concerning the function of the N-terminal region in *tra* RNA alternative splicing regulation. While it has been proposed that this region is not necessary for *tra* regulation (Granadino *et al.*, 1997), others have proposed the opposite (Yanowitz *et al.*, 1999). Differences in how the different groups have performed the experiments, which include different constructs (40aa deletion of the N-terminal region in one case and 94aa in the other), use of different promoters, and different real-time polymerase chain reaction (RT-PCR) methods to detect the splice forms, might explain the discrepancy.

The genes *female-lethal-2-d* (*fl(2)d*) (Granadino *et al.*, 1996) and *virilizer* (*vir*) (Hilfiker *et al.*, 1995) are also required for female-specific splicing of the *tra* pre-mRNA. Genetic analyses have ruled out a direct role of *sans-fille* (*snf*) in *tra* pre-mRNA splicing (Cline *et al.*, 1999).

1.1.1.3.4. The role of *doublesex, hermaphrodite,* and *intersex* in sex determination At the bottom of the sex determination gene cascade are the genes *dsx*, *her*, and *ix*, which are expressed in both sexes.

The *dsx* pre-mRNA contains six exons: three common exons (E1–E3), a female-specific exon (E4), and two male-specific exons (E5–E6) (**Figure 7**). In females, the Tra^F protein, together with the constitutive Tra-2 protein (Goralski *et al.*, 1989; Amrein *et al.*, 1990; Mattox *et al.*, 1990), directs the splicing of the *dsx* pre-mRNA to the female mode. The mRNA produced contains exons E1, E2, E3, and E4 and gives rise to the female Dsx^F protein, which promotes female sexual development. In males, where no functional Tra protein is available, the *dsx* pre-mRNA follows the male mode of splicing that gives rise to mRNA containing exons E1, E2, E3, E5, and E6, which produces male Dsx^M protein, which promotes male sexual development (Burtis and Baker, 1989; Hoshijima *et al.*, 1991) (**Figure 7**). A further component that is crucial in the sex-specific splicing of *dsx* pre-mRNA, is the splicing enhancer *dsx*RE (*doublesex* repeat element) placed in the female-specific exon E4, 300 nt downstream of the 3′ splice site (review: Maniatis, 1991). Six copies of a 13 nt repeat together with a purine-rich element (PRE) located between repeats 5 and 6, make up the *dsx*RE enhancer (Burtis and Baker, 1989; Lynch and Maniatis, 1996).

The sequent of the female-specific 3′ splice site in intron 3 departs significantly from the consensus 3′

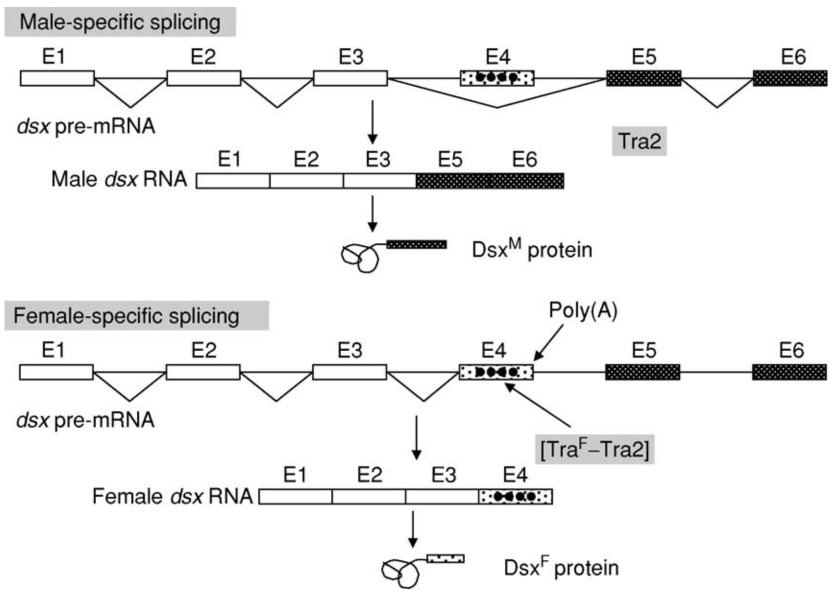

Figure 7 Sex-specific splicing of *dsx* pre-mRNA. Boxes and thin lines represent exons (E1–E6) and introns, respectively. The dots inside exon E4 represent the *dsx*RE enhancer to which the Tra^F–Tra2 complex binds. Poly(A) indicates the polyadenylation site of the mRNA arising from female-specific splicing.

splice site and is weaker than the 3′ splice site of the downstream intron 4. In males, the splicing machinery recognizes the 3′ splice site of intron 4 instead of the 3′ splice site of intron 3. Consequently, the male splicing follows and Dsx^M protein is produced. In females, however, because of the presence of Tra^F protein, Tra^F and Tra2, as well as the SR-protein RBP1, form a complex that binds to the *dsx*RE enhancer. This complex recruits U2AF and possibly other components of the general splicing machinery to the *dsx* pre-mRNA causing the splicing machinery to recognize the 3′ splice site of intron 3 instead of the 3′ splice site of intron 4. Consequently, female splicing follows and Dsx^F protein is produced (Hedley and Maniatis, 1991; Inoue *et al*., 1992; Tian and Maniatis, 1993, 1994; Zuo and Maniatis, 1996; Du *et al*., 1998; Nikolakaki *et al*., 2002). The activity and localization of the Tra^F, Tra-2, and RBD1 proteins depend on the activity of the LAMMER kinase encoded by the gene *Darkener of apricot* (*Doa*) (Du *et al*., 1998; Yun *et al*., 2000; Nikolakaki *et al*., 2002).

The two Dsx proteins, Dsx^F and Dsx^M, are transcription factors controlling the activity of the final target genes involved in sexual differentiation. The two proteins share the N-terminal domain, which contains a DNA-binding domain (DM domain), whereas they differ at their C-terminal domains, which endow these proteins with their specific function (Burtis and Baker, 1989; Hoshijima *et al*., 1991).

The *her* gene encodes a zinc finger protein, which endows to this protein the capacity to bind DNA, so that Her can function as a transcription factor (Li and Baker, 1998a). This agrees with the dual function shown by the *her* gene. Its maternal expression is necessary for early *Sxl* activation (see Section 1.1.1.2.5), while its zygotic expression is necessary for female terminal differentiation and some aspects of male terminal differentiation (Pultz and Baker, 1995; Li and Baker, 1998b).

The Dsx and Her products act either independently or interdependently to control different sexual differentiation processes. Thus, for example, the *yolk protein* (*yp*) genes *yp1* and *yp2* are the best-characterized female terminal differentiation genes. The expression of the *yp1* and *yp2* genes is under the control of gene *dsx* in the fat body (review: Bownes, 1994). Dsx^F and Dsx^M directly activate and inhibit the *yp* genes, respectively. They exert their function through the fat body specific enhancer (FBE). It has been found that in females, Dsx^F and Her independently activate the *yp* genes and that Her acts through sequences different than those of the FBE enhancer (Li and Baker, 1998b). In males, Dsx^M prevents the activation of *yp* genes by Her (Li and Baker, 1998b). However, the genes *dsx* and *her* also function interdependently to control the female differentiation of the sexual dimorphic foreleg bristles and the pigmentation of the 5th and 6th tergites (Li and Baker, 1998b).

The *ix* gene is transcribed in both sexes and its pre-mRNA does not follow a sex-specific splicing, indicating that the Ix protein is present in both sexes. Ix shows similarity to proteins thought to

act as transcriptional activators, although a DNA-binding domain has yet to be identified (Garrett-Engele *et al*., 2002). By means of the yeast-2 hybrid and coimmunoprecipitation analyses, it has been possible to demonstrate that Ix interacts with Dsx^F but not Dsx^M. In addition, by gel shift analysis it has been shown that Ix and Dsx^F form a DNA-binding complex (Garrett-Engele *et al*., 2002).

Ix also participates in the control of *yp* gene expression through the FBE enhancer (Garrett-Engele *et al*., 2002). Ectopic expression of Dsx^F in *ix* mutant males is not sufficient to induce expression of the *yp* genes, indicating that Dsx^F requires *ix* function to activate the *yp* genes (Waterbury *et al*., 1999). Collectively, these results suggest that Ix and Dsx^F form a complex to control female terminal differentiation.

1.1.1.4. Sex Determination Genes in Other Dipteran and Nondipteran Species

The search for genes homologous to sex determination genes of *D. melanogaster* has been undertaken. Among the genes that form the X/A signal, gene *sc* of *D. subobscura* (Botella *et al*., 1996) and gene *sis-a* of *D. pseudoobscura* and *D. virilis* (Erickson and Cline, 1998) have been characterized. These genes display a significant conservation in their structure and function.

The *Sxl* gene has also been characterized in different *Drosophila* species. The structure and sequence organization of *Sxl* of *D. virilis* (Bopp *et al*., 1996) and *D. subobscura* (Penalva *et al*., 1996) have been determined. Like in *D. melanogaster*, *Sxl* regulation occurs by sex-specific alternative splicing: the *Sxl* transcripts in males have an additional exon containing stop translation codons. The *Sxl* of *D. virilis*, however, is unusual due to the presence in males of an open reading frame, downstream of the last stop codon in the male-specific exon, which encodes an Sxl protein. This is identical to the female Sxl protein except for the first 25 amino acids of the amino terminal region, which are encoded by differentially spliced exons. The male Sxl protein is predominantly accumulated in the embryonic ectoderm, suggestive of a putative role in the development of the central nervous system (Bopp *et al*., 1996). Sxl protein was also detected in males of other species (*D. americana, D. flavomontana*, and *D. borealis*) of the *virilis* radiation (Bopp *et al*., 1996).

Outside the genus *Drosophila*, *Sxl* has been characterized in *Chrysomya rufifacies* (Müller-Holtkamp, 1995), *Megaselia scalaris* (Sievert *et al*., 1997, 2000), *Musca domestica* (Meise *et al*., 1998) and *Ceratitis capitata* (Saccone *et al*., 1998), which belong to the Brachycera Suborder, and in *Sciara ocellaris* (Ruiz *et al*., 2003) which belongs to the Nematocera Suborder. Particularly interesting is the case of *S. ocellaris*, where as in *D. melanogaster*, gender depends on chromosome constitution: females are XX and males are X0 (Gerbi, 1986). Further, dosage compensation in *Sciara* appears to be achieved by hypertranscription of the single male X chromosome (da Cunha *et al*., 1994). The *Sxl* gene of all these species shows two main properties. First, *Sxl* is not regulated in a sex-specific fashion. Second, the Sxl proteins of the nondropsophilid and drosophilid species show a great degree of conservation in the two RBD domains and the few amino acids that separate them (the linker region). However, a high degree of conservation is not found outside these two domains. Collectively, these results suggest that the *Sxl* gene may not play the master regulatory role in sex determination in the non-drosophilids, as is the case with the *Drosophila* genus. This further suggests that *Sxl* was coopted to become the master regulatory gene in sex determination and dosage compensation during the evolution of the *Drosophila* lineage.

The *tra* genes in the species that belong to the *melanogaster* group, *D. simulans, D. mauritiana*, *D. sechellia*, and *D. erecta* (O'Neil and Belote, 1992; Kulathinal *et al*., 2003), and *D. hydei* and *D. virilis* (O'Neil and Belote, 1992) have also been characterized. Its comparison with *tra* of *D. melanogaster* revealed an unusually high degree of divergence, yet the heterologous genes can rescue *tra* mutations in *D. melanogaster*. The gene *tra-2* of *D. virilis* has been characterized as well (Chandler *et al*., 1997). It encodes a set of protein isoforms analogous to those of *D. melanogaster*, and it can rescue the *tra-2* mutations in this species.

Outside the genus *Drosophila*, *tra* has been characterized in *C. capitata* (Pane *et al*., 2002). Like in *D. melanogaster*, alternative splicing regulates the *Ceratitis tra* gene, so that only females contain a full-length protein. In contrast to *Drosophila* where *Sxl* regulates *tra*, however, the *tra* gene of *Ceratitis* shows an autoregulatory function that produces functional protein specifically in females. Therefore, *tra* in *Ceratitis* constitutes a cellular memory devise that maintains the female developmental pathway.

The *dsx* genes of *Megaselia scalaris* (Sievert *et al*., 1997), *Bactrocera tryoni* (Shearman and Frommer, 1998), *Bombyx mori* (Ohbayashi *et al*., 2001; Suzuki *et al*., 2001), and *Musca domestica* (Hediger and Bopp, cited in Schütt and Nöthiger, 2000) and *C. capitata* (Saccone *et al*., cited in Pane *et al*., 2002) have been characterized as well. In these species, *dsx* encodes male- and female-specific RNAs, which encode putative male- and female-specific Dsx

proteins sharing the N-terminal region and differing at their C-terminal regions, like in *Drosophila*. Unlike the *Drosophila* case, however, the female-specific intron in *Bombyx dsx* does not show a weak 3′ splice site, and the Tra–Tra2 binding sequences (corresponding to the *dsx*RE enhancer in *Drosophila*; see Section 1.1.1.3.4) were not found. This suggests that the female-specific splicing of *dsx* pre-mRNA is the default splicing mode in *Bombyx*, in contrast to *Drosophila*, where the default splicing is male-specific.

Collectively, these results agree with the model of Wilkins (1995), who proposed that during evolution, the sex-determining cascades were built from bottom to top, with the genes at the bottom being more conserved than the more upstream genes in the cascade.

1.1.2. The Development of the Genital Disc of *Drosophila*

1.1.2.1. Historical Overview

The imaginal discs of *D. melanogaster* are good experimental models for the study of developmental processes (Nöthiger, 1972). Imaginal discs are formed by invagination from the embryonic ectoderm as pouches of cells and remain connected to the larval tissue until metamorphosis. They grow by cell division during the larval stages, whereby they acquire their patterning and typical shape. At the end of the larval period, each mature imaginal disc appears as an assembly of sets of spatially arranged cells with distinct determination states (patterning). These differentiate during metamorphosis as a response to hormonal stimulus (ecdysone). The result is the formation of the adult epidermal structures, such as the eye, antenna, leg, wing, and terminalia. Although these structures differ in appearance, the mechanisms controlling their growth and patterning, and even the genes involved, are very similar.

The genital disc forms the terminalia, which comprise the entire set of internal and external genitalia and analia, the most sexually dimorphic structures in the adult (**Figure 8**). This disc shows certain characteristics that distinguish it from other imaginal discs. There are two imaginal discs, one for the right and one for the left, for each of the adult appendage except for the terminalia, which are derived from a single genital disc. The cells that form the genital disc are recruited from different segments in the embryo (see Section 1.1.2.3.1), whereas the other discs (with the exception of the eye–antenna disc) are formed by cells derived from single segments. Because of these characteristics, the genital disc is well suited for studying developmental processes, such as the recruitment of cells to form complex structures and the control of patterning. Most importantly, however, the genital disc shows a unique feature. All imaginal discs except the genital one produce the same specific single adult appendage in both males and females. Thus, the eye, antenna, leg, wing, and haltere imaginal discs produce the corresponding adult structures in both sexes. In contrast, the genital disc has the potential to develop into either male or female terminalia, which are composed of different structures (**Figure 8**). Thus, the genital disc is a very good experimental model for the study of how sex determination genes, together with the homeotic ones – which determine cell identity – form an integrated genetic input that directs the development of a population of cells into two distinct, male or female, adult structures (reviews: Sánchez and Guerrero, 2001; Christiansen *et al*., 2002).

The complex organization of the genital disc was revealed through the analysis of gynandromorphs, flies composed of male (X0) and female (XX) cells. These animals allow the construction of fate maps concerning the relative position of the blastoderm founder cells for the different structures that compose the adult cuticle. The use of gynandromorphs to construct fate maps is based on an idea developed by Sturtevant (1929), who performed an analysis of gynandromorphs and calculated the frequencies with which two parts in the adult fly had different sexual phenotypes; i.e., whether they were formed by X0 or XX cells. The main conclusion was that the frequency with which the X0/XX border run between two parts was directly related to the distance of these parts in the adult and to the proximity of their founder blastoderm cells in the embryo (Janning, 1978).

Dobzhansky (1931) and Kröger (1959) used gynandromorphs for the first time to determine the origin of the sexually dimorphic structures derived from the genital disc (**Figure 8**). These authors assumed that the male and female terminalia were homologous; i.e., the cells that composed the genital disc primordium have the capacity of developing along two alternative, male or female, pathways. Thus, cells with a X0 genetic constitution formed male terminalia, whereas cells having an XX constitution produced female terminalia. Under this assumption, it was expected to find a set of gynandromorphs that would cover a whole spectrum of terminal structures, ranging from pure male to pure female terminalia, through cases displaying different mixtures of pure male and female structures. The prerequiste to be fulfilled was that in the

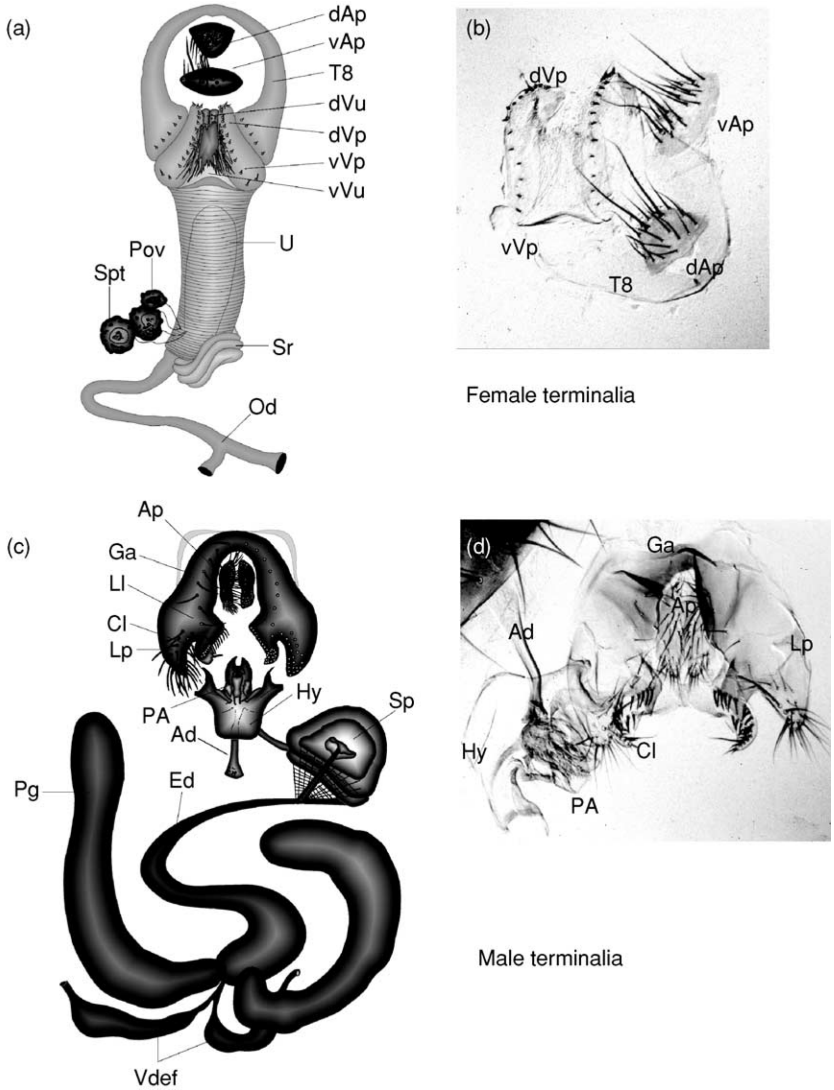

Figure 8 Scheme showing all the adult derivatives of the genital disc in both sexes ((a) female; (c) male) and photographs of external adult structures ((b) female; (d) male). External female terminalia: dAp, dorsal anal plate; vAp, ventral anal plate; T8, tergite eight; dVu, dorsal vulva; vVu, ventral vulva; dVp, dorsal vaginal plate; vVp, ventral vaginal plate. Internal female terminalia: U, uterus; Sr, seminal receptacle; Spt, spermatheca; Pov, parovaria; Od, oviduct (it is connected to the ovaries). Male external terminalia: Ap, anal plate; Ga, genital arch; Ll, lateral lobe; Lp, lateral plate; Cl, clasper; PA, penis apparatus; Ad, apodeme; Hy, hypandrium. Internal male terminalia: Ed, ejaculatory duct; Sp, sperm pump; Pg, paragonia (male accessory gland); Vdef, *vas deferens* (it is connected to the testes).

gynandromorphs the male and female structures should add up to a complete terminalia. However, Dobzhansly and Kröger noticed that this was not the case.

Nöthiger *et al.* (1977) addressed this question again more recently by analyzing the derivatives of mosaic genital discs of gynandromorphs. Their results constituted a benchmark in the comprehension of the organization and development of the genital disc. They found that, in the majority of the gynandromorphs, the male and female analia behave as expected if both were homologous and derived from a common population of cells: the male and female anal structures added up to a complete analia. In contrast, the male and female genitalia yielded different results, as any female external genital structure could be combined with any male external structure. Furthermore, gynandromorphs were found that either lacked completely an external genital structure or had two external genitalia – a complete set of male and female structures. These observations applied not only to the external terminalia but also to the internal genital structures. The data were explained by the proposal

that the genital disc is composed of three primordia: two separate primordia for the male and female genitalia, respectively, and a third one for the analia. The development of each genital primordium is either allowed or blocked depending on the chromosome constitution of their component cells. In X0 individuals, the male primordium develops to form the male genitalia and the development of the female primordium is blocked. In XX individuals, the female primordium develops to form the female genitalia, while the development of the male genital primordium is inhibited. However, the analia will always develop, giving rise to either male or female anal structures depending on the chromosome constitution of their cells, X0 or XX, respectively (but see below).

According to this hypothesis the relative position of the three primordia that form the genital disc would be such that the female genital primordia occupies the most anterior position, the anal primordium occupies the most posterior position, and the male genital primordium is placed in the middle. This organization was suggested by the appearance of gynandromorphs lacking genitalia and having a female analia, and gynandromorphs that had complete female and male genitalia as well as male analia. In both classes of gynandromorphs, the X0/XX border runs between the female and the male genital primordia (**Figure 9**). In the first class, X0 cells populate the female genital primordium, whereas XX cells populate the male genital and anal primordia. Consequently, the female and male genital primordia do not develop, whereas the anal primordium develops and produces a female analia. In the second class of gynandromorphs, the XX cells populate the female genital primordium whereas X0 cells populate the male genital and anal primordia. Consequently, the female genital primordium develops to produce complete female genitalia, whereas the male genital primordium develops and produces complete male genitalia, while the anal primordium develops and produces male analia.

The hypothesized organization of the three primordia in the genital disc was confirmed when the disc's embryonic origin was analyzed (Schüpbach *et al*., 1978). It was found that the genital disc arises from a group of cells in the ventral side of the embryo. Within this group, three regions can be distinguished that are present in both sexes: an anterior region that gives rise to the female genitalia, a medial region that gives rise to the male genitalia, and a posterior one that produces the analia. Collectively, these data support the model that the genital disc is composed of three primordia: the female genital primordium (FGP) located anteriorly, the anal primordium (AP) located posteriorly, and the male genital primordium (MGP) placed in between (**Figure 9**).

In each sex, only one of the two genital primordia develops depending on its sexual genotype, whereas the other remains in a so-called "repressed state," and

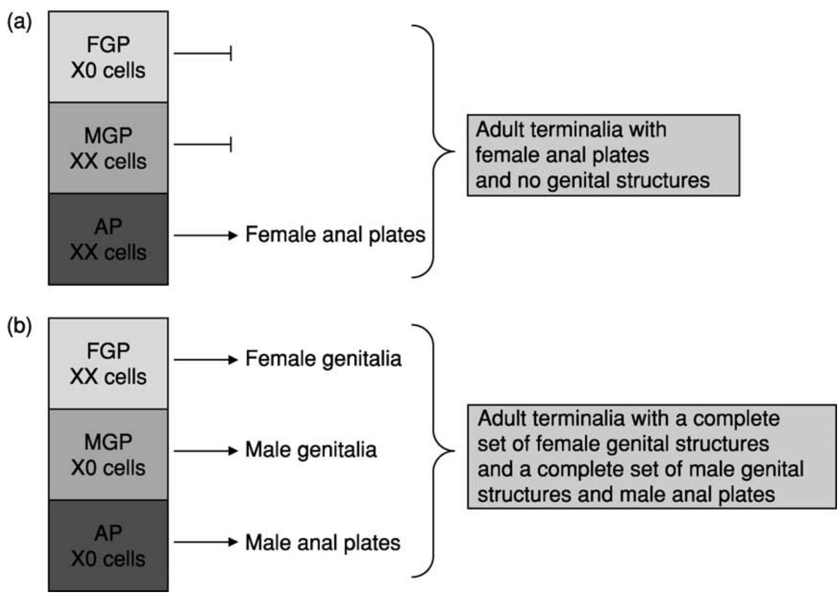

Figure 9 Gynandromorphs lacking genitalia and having female analia (a), and gynandromorphs that have complete female and male genitalia plus male analia (b). In both classes of gynandromorphs, the X0/XX border runs between the female and the male genital primordia. FGP, female genital primordium; MGP, male genital primordium; AP, anal primordium. See text for explanation.

does not form a recognizable adult structure (but see below). The "repressed" FGP in a male genital disc is termed RFP, and the "repressed" MGP in a female genital disc is termed RMP. In females, Dsx^F promotes the development of both the female genital and anal primordia, giving rise to the female genitalia and analia respectively; whereas the development of the male genital primordium is brought into the "repressed state" (RMP) (**Figure 10**). In normal males, Dsx^M promotes development of both the male genital and anal primordia, giving rise to the male genitalia and analia respectively, whereas the development of the female genital primordium is brought into the "repressed state" (RFP) (**Figure 10**). Mutations of the *dsx* gene, that do not produce Dsx^F and Dsx^M products, result in the generation of genital discs that show the same type of intersexual development in both 2X;2A and XY;2A flies. The latter is characterized by the development of both male and female genital primordia (though neither produce a complete set of genital structures) and by the anal primordium forming intersexual analia (Ehrensperger, 1983). The same intersexual development is observed when both Dsx^F and Dsx^M are simultaneously present within a cell (Epper, 1981) (**Figure 10**). This situation is encountered in 2X;2A flies of genotype dsx^+/dsx^D, where the dsx^+ allele produces the Dsx^F protein and the dsx^D allele produces the Dsx^M protein (Nagoshi and Baker, 1990).

The demonstration that the RFP corresponds to the FGP (i.e., the localization of the RFP in the male genital disc) and that the RMP corresponds to the MGP (i.e., the localization of the RMP in the female genital disc) was performed by the analysis of intersexual genital discs and the clonal analysis of *tra* mutations. Thus:

1. The XX; $dsx^D/+$ (Epper, 1981) and XX; *dsx/dsx* or XY; *dsx/dsx* or XX; *ix/ix* (Ehrensperger, 1983) intersexual genital discs contain three major regions (ventral, anterior dorsal, and posterior dorsal), which were isolated by fragmentation and transplanted into mature larvae ready to pupate, such that they underwent metamorphosis. The ventral fragment produced female genital structures, the dorsal anterior fragment produced male genital structures, and the dorsal posterior fragment produced anal structures. The ventral fragment of the intersexual genital disc corresponds to the region of the normal male genital disc that does not develop; i.e., to the RFP. The dorsal anterior fragment of the intersexual genital disc corresponds to the region of the normal female genital disc that does not develop; i.e., to the RMP.
2. The *tra* mutation transforms chromosomal (XX) females into males (see above). Clones homozygous for *tra* were induced by X-irradiation of

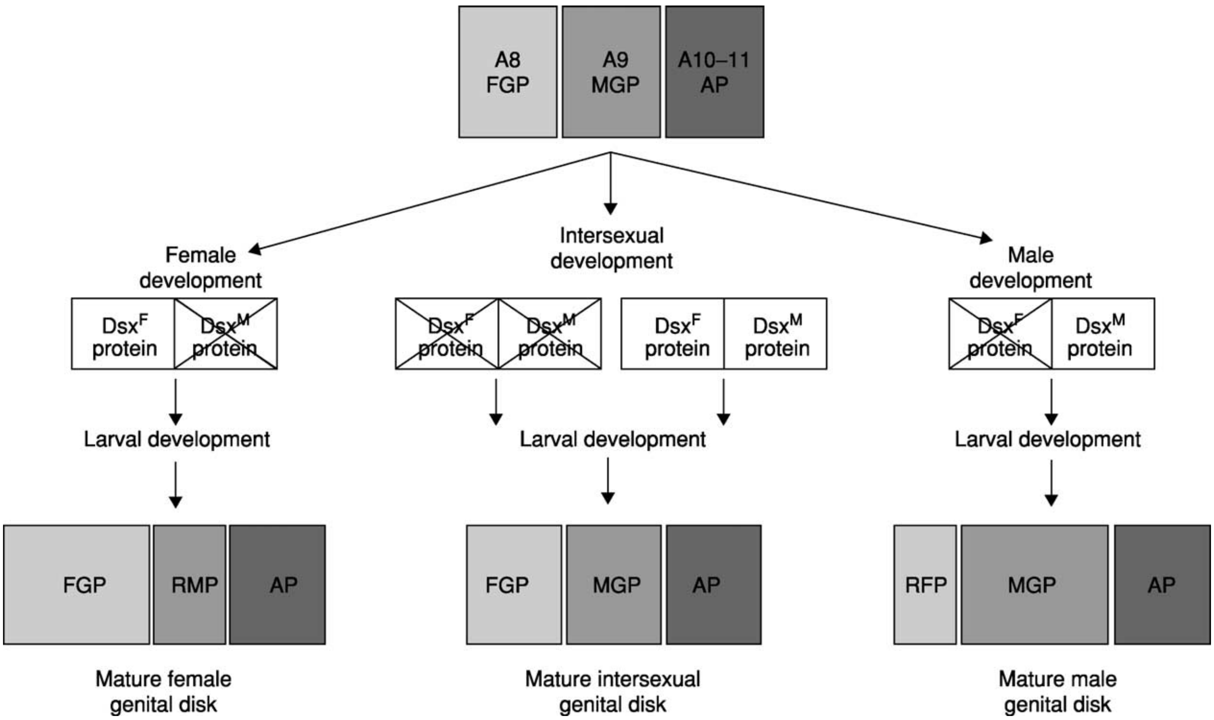

Figure 10 Sexually dimorphic development of the genital disc. A8, A9, and A10–11 indicate the corresponding abdominal segments. For further explanations on the role of Dsx, see text.

XX; *tra*/+ larvae at late third larval instar. The genital discs were dissected and cultured *in vivo* in the abdomen of fertilized females to allow them to grow further before metamorphosis. Thereafter, the implants were dissected and, in a significant number of cases, the genital discs showed local overgrowths, at the site of the RMP in the female genital disc. These overgrowths were cut out of the discs and transplanted into larvae that underwent metamorphosis. All of them produced male genital structures. These results suggest that the RMP corresponds to the male genital primordium of the female genital disc that does not develop and that the *tra* function is needed to prevent development of the RMP (Epper and Nöthiger, 1982).

The cell lineage relationships between the primordia that compose the genital disc were studied by clonal analysis in the male and female genital discs. It was shown that clones overlapped in the right and left sides in both genital discs, but no clones were found that comprised genital and anal structures. This indicates that there is a cell lineage restriction between the analia and the genitalia in both sexes (Schüpbach *et al*., 1978; Dübendorfer and Nöthiger, 1982; Janning *et al*., 1983). No cell lineage restriction between the two genital primordia could be determined, since in each sex only one of the primordia develops (but see Section 1.1.1.2.2).

1.1.2.2. Embryonic Organization of the Genital Disc

As mentioned above, the embryonic region of the genital disc contains three different regions (**Figure 11**). The anterior region that contains precursors for the female genital primordium (FGP) corresponds to abdominal segment A8. The central region that contains precursors for the male genital primordium (MGP) corresponds to segment A9. And the most posterior region that gives rise to the analia of both males and females corresponds to segments A10 and A11 (Schüpbach *et al*., 1978) (**Figure 11**).

The embryonic genital disc can be distinguished at about 12 h of development by the expression of *headcase* (*hdc*) and *escargot* (*esg*), which mark all imaginal cells (Whiteley *et al*., 1992; Weaver and White, 1995; Casares *et al*., 1997). According to genetic mosaic analysis conclusions, the embryonic genital disc contains 12–15 cells (Hartenstein and Jan, 1992) that are organized as three clusters: two of them located to the left and right of the midline, and the other located posteriorly. These clusters do not correspond to the three primordia of the genital

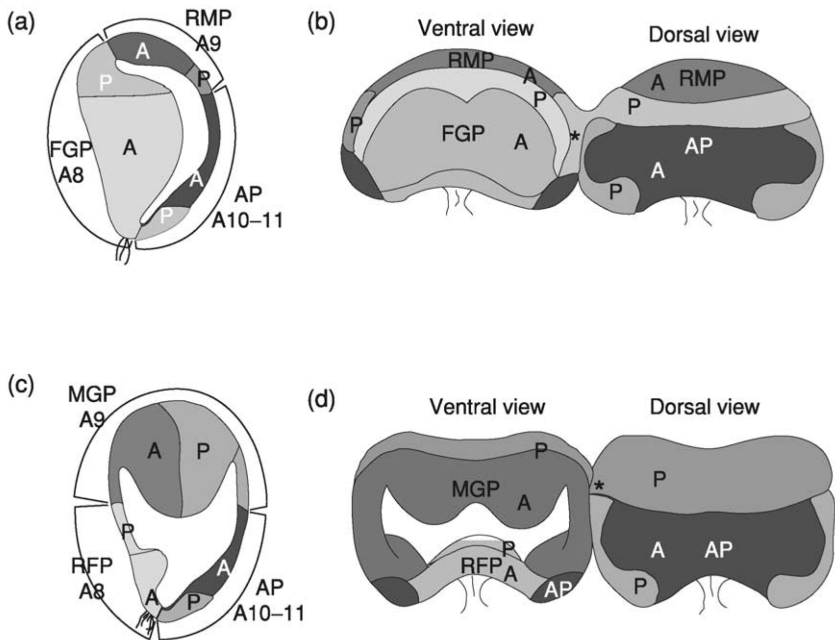

Figure 11 Schematic representation of the compartmental organization of the female and male genital disc. Transverse sections (a, c) and dorsal and ventral view of (b, d) of the female (a, b) and male (c, d) genital disc respectively. Developing female genital primordium (FGP) or repressed female genital primordium (RFP) is in light gray; developing male genital primordium (MGP) or repressed male genital primordium (RMP) is in gray, and anal primordium (AP) is in dark gray. In each case, the anterior compartment (A) is lighter than the posterior compartment (P). The asterisk indicates that the P compartment cells of the three genital primordia are contiguous. For the rest of the symbols see legend to **Figures 8** and **9**.

disc; in fact, the tripartite organization of the genital disc is not obvious in the embryo (Casares *et al.*, 1997). The genital disc grows during larval stages to give the sexually dimorphic disc characteristic of the third instar larvae.

1.1.2.3. Organization and Patterning of the Genital Disc during Larval Development

1.1.2.3.1. Segmental and compartmental organization of the genital disc As was previously described, early studies have demonstrated the existence of a cell lineage restriction between the analia and male or female genitalia (Schüpbach *et al.*, 1978; Dübendorfer and Nöthiger, 1982; Wieschaus and Nöthiger, 1982). Initially, the question of a clonal restriction between male and female genitalia could not be addressed, because only one of the two genital primordia gives rise to adult structures in any one sex. Although it is now known that the RMP in females gives rise to the parovaria and that the RFP in males gives rise to a miniature 8th tergite (Keisman and Baker, 2001; see also below), these structures cannot be marked in the adult and are not suitable for analysis of clonal relationships. A cell lineage restriction analysis using dsx^1 genital discs, where both primordia develop, has shown that clones could not cross the border between female and male genitalia (Gorfinkiel *et al.*, 2003). Therefore, it was concluded that a cell lineage restriction exists between female and male genitalia, and between genitalia and analia. The evidence suggests that the three primordia of the genital disc represent three originally separate abdominal segments.

Each primordium of the genital disc has an anterior and a posterior compartment, which can be marked by the reciprocal expression of the *cubitus interruptus* (*ci*) and *engrailed* (*en*) genes (Freeland and Kuhn, 1996; Casares *et al.*, 1997; Chen and Baker, 1997) (**Figure 12**). The *ci* and *en* mRNAs label the anterior and posterior compartments, respectively, and mark correspondingly the cells in all imaginal discs (Kornberg *et al.*, 1985; Eaton and Kornberg, 1990). This agrees with *en* mutations affecting both male and female genitalia plus analia (Lawrence and Struhl, 1982; Epper and Sánchez, 1983). The analysis of *en* loss-of-function clones has shown that the majority of external genital structures are of anterior origin (Casares *et al.*, 1997; Emerald and Roy, 1998). Clones induced at the second larval stage do not cross between *en* mRNA- and *ci* mRNA-expressing cells (Chen and Baker, 1997) suggesting that at least by the beginning of the second instar, the genital disc has already subdivided into anterior and posterior compartments.

A striking recent finding has challenged the idea that imaginal genital discs have, like all other imaginal discs, only anterior and posterior compartments. Ahmad and Baker (2002) have found a group of cells in the male genital primordium that express the *breathless* (*btl*) gene, which encodes the fibroblast growth factor receptor. These cells define a novel (third) compartment, because they do not express either *ci* or *en* and clones do not cross between *btl*-expressing cells and the rest of the disc. Surprisingly, these *btl*-expressing cells are not originally part of the male genital disc but are recruited into it during

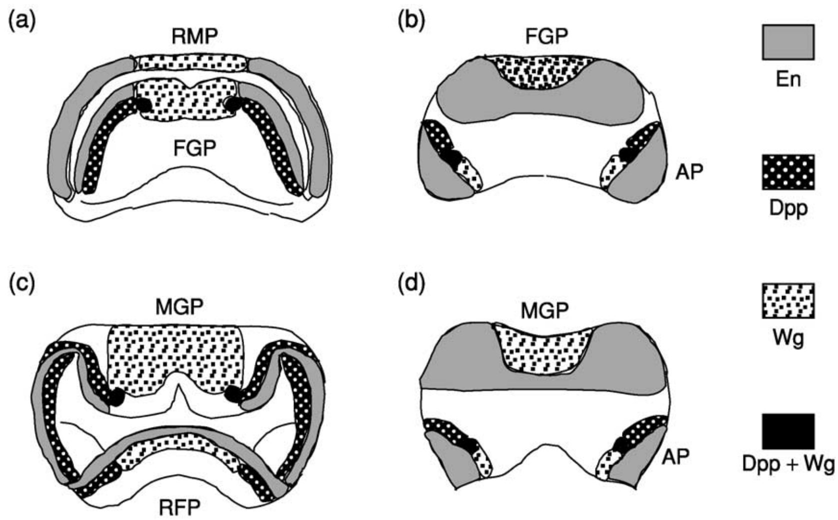

Figure 12 Expression patterns of En, Dpp, and Wg in the female (a, b) and male (c, d) genital discs. The cells coexpressing Wg and Dpp are shown in black. (a) and (c) are ventral views, (b) and (d) are dorsal views of the corresponding genital discs. For the symbols see legend to **Figures 9** and **11**.

the larval stages. Cells in the male genital primordium expressing the gene *branchless* (*bnl*), which encodes the fibroblast growth factor, induce the *btl*-expressing mesodermal cells to migrate into the male disc. In this process, they lose the mesodermal marker *twist* (*twi*), acquire the ectodermal marker *coracle* (*cora*) and, eventually, form the paragonia. Therefore, three compartments compose the male genital primordium.

Are the segmental borders different than the compartment borders? The genital disc is a good model to address this question, since the three primordia are contiguous to each other, like in the abdomen. It has been shown that in the wing disc, the Hedgehog (Hh) signaling pathway is responsible for the maintenance of the compartment border (see **Chapter 1.9**). *smoothened* (*smo*) anterior clones, which are unable to transduce the Hh signal, mix freely with posterior cells (Blair and Ralston, 1997; Rodriguez and Basler, 1997). In the genital disc, *smo* anterior clones can also mix with posterior cells but only from the same segment; *smo* anterior cells from one segment cannot mix with posterior cells from another segment (although they are contiguous). This lineage restriction does not depend on homeotic function either, although it cannot be ruled out that homeotic genes fix the restriction border much earlier during embryonic development (Gorfinkiel *et al.*, 2003). Altogether, it can be concluded that segmental borders are different from the compartment borders.

1.1.2.3.2. Inductive signals in the development of the genital disc In the past decade, a paradigm has arisen about the genetic organization of imaginal discs. The selector gene *en* is expressed in posterior cells and activates the signal molecule Hh, which diffuses into the anterior compartment and elicits the activation of target genes. In the wing disc, Hh activates the expression of *decapentaplegic* (*dpp*), while in the leg and antennal disc, it activates de expression of *dpp* in dorsal anterior cells and *wingless* (*wg*) in ventral anterior cells. Both *wg* and *dpp* are signaling molecules that specify different identities in a concentration-dependent manner (reviews: Campbell and Tomlinson, 1995; Lawrence and Struhl, 1996) (see also **Chapter 1.9**).

The same interactions take place in the genital disc, where each primordium is organized in a manner similar to that of the leg and antennal discs (Freeland and Kuhn, 1996; Casares *et al.*, 1997; Chen and Baker, 1997; Sánchez *et al.*, 1997; Gorfinkiel *et al.*, 1999). In the genital and anal primordia, *en* in the posterior compartment activates the expression of *hh*, which, in turn, activates the expression of *wg* and *dpp* in mutually exclusive and complementary domains, except in the A9 of female discs where *dpp* is not expressed (Freeland and Kuhn, 1996; Casares *et al.*, 1997; Sánchez *et al.*, 1997) (**Figure 12**). As it has been demonstrated in the leg disc (see **Chapter 1.9**), *wg* and *dpp* inhibit each other's expression (Sánchez *et al.*, 1997).

The analysis of the expression domains of *wg* and *dpp* in the adult and the phenotypes obtained from lack of function and/or ectopic function of these signaling molecules have allowed the determination of the genital structures specified by these genes. Thus, in males, *wg* is expressed in the penis apparatus, the claspers, and the genital arch (Sánchez *et al.*, 1997). A requirement for *wg* in the development of these structures has been confirmed by the phenotype of *wg* hypomorphic alleles (Chen and Baker, 1997; Gorfinkiel *et al.*, 2003). In females, the dorsal vaginal plates express high levels of *wg* and can be duplicated by ectopic expression of *wg*, suggesting that Wg specifies these structures (Chen and Baker, 1997; Sánchez *et al.*, 1997). The vulva has been found to require *wg* function also (Gorfinkiel *et al.*, 2003). In addition, *wg* is required for the development of the internal genitalia in both sexes (Chen and Baker, 1997). The *dpp* gene is expressed also in the vaginal plates in females and in a subset of structures of the male genitalia like the genital arch, the hypandrium, and also the claspers (Sánchez *et al.*, 1997).

The analysis of hypomorphic combinations of *dpp* has shown that *dpp* is required for all the genital structures except for the penis apparatus (Gorfinkiel *et al.*, 2003). Furthermore, it has been shown that *optomotor-blind* (*omb*), a downstream gene in the *dpp* pathway (Grimm and Pflugfelder, 1996), is required for the formation of the dorsal bristles of the claspers and the hypandrium bristles (Gorfinkiel *et al.*, 1999). It is also known that *dachshund* (*dac*), which is a downstream gene of *wg* in females but a downstream gene of *dpp* in males (Keisman and Baker, 2001; Sánchez *et al.*, 2001) (see Section 1.1.2.4.1), is required for proper formation of the internal ducts that connect the spermathecae to the uterus in females, and for correct formation of the claspers in males (Gorfinkiel *et al.*, 1999; Keisman and Baker, 2001).

The assignment of a particular signaling pathway to a specific adult structure is difficult because the Wg and Dpp pathways also act coordinately to activate downstream genes that, in turn, specify different structures. For example, the expression of *Distal-less* (*Dll*) is activated by the coordinated action of *wg* and *dpp* (Gorfinkiel *et al.*, 1999), as happens in the leg disc (Díaz-Benjumea *et al.*, 1994)

(see **Chapter 1.9**). *Dll* has been identified as a gene required for leg development and, in the terminalia, it is required for the development of the anal plates in both males and females (Sunkel and Whittle, 1987; Cohen and Jürgens, 1989; Gorfinkiel *et al*., 1997, 1999).

1.1.2.3.3. Homeotic identity of the genital disc primordia The homeotic (Hox) genes specify structures along the anterior–posterior axis in most multicellular organisms (see **Chapter 1.8**). In *Drosophila*, the homeotic genes *abdominal-A* (*abd-A*), *Abdominal-B* (*Abd-B*), and *caudal* (*cad*) specify the identity of the three posterior primordia (**Figure 13**). The *abd-A* gene is expressed in part of the A8 primordium; in females this region correspond to the internal genitalia (Freeland and Kuhn, 1996). Based on its expression domain, it appears that *abd-A* is not required for the formation of the external genitalia (Sánchez-Herrero *et al*., 1985; Tiong *et al*., 1985). The *Abd-B* gene has two transcripts: *Abd-Bm* and *Abd-Br*, which encode two proteins differing from each other in their N-terminal region. The m transcript is expressed in the A8 primordium, while the r transcript is expressed in the A9 primordium (Casares *et al*., 1997). The complete lack of *Abd-B* expression transforms the genitalia into leg or distal antenna, and this transformation is accompanied by ectopic expression of *Dll* and *dachshund* (*dac*), two genes required for leg development (Estrada and Sánchez-Herrero, 2001) (see **Chapters 1.8** and **1.9**). Conversely, ectopic *Abd-B* expression transforms parts of the head into genitalia (Postlethwait *et al*., 1972; Kuhn *et al*., 1995). It has been suggested that the role of *Abd-B* is to specify genitalia by repressing *Dll* activity (Estrada and Sánchez-Herrero, 2001). As *Dll* is activated by the combined action of *wg* and *dpp* in the genital disc, the role of *Abd-B* would be to counteract the activating function of these two signaling molecules. Because high levels of ectopic Dll are able to induce ventral appendages, legs, or antennae

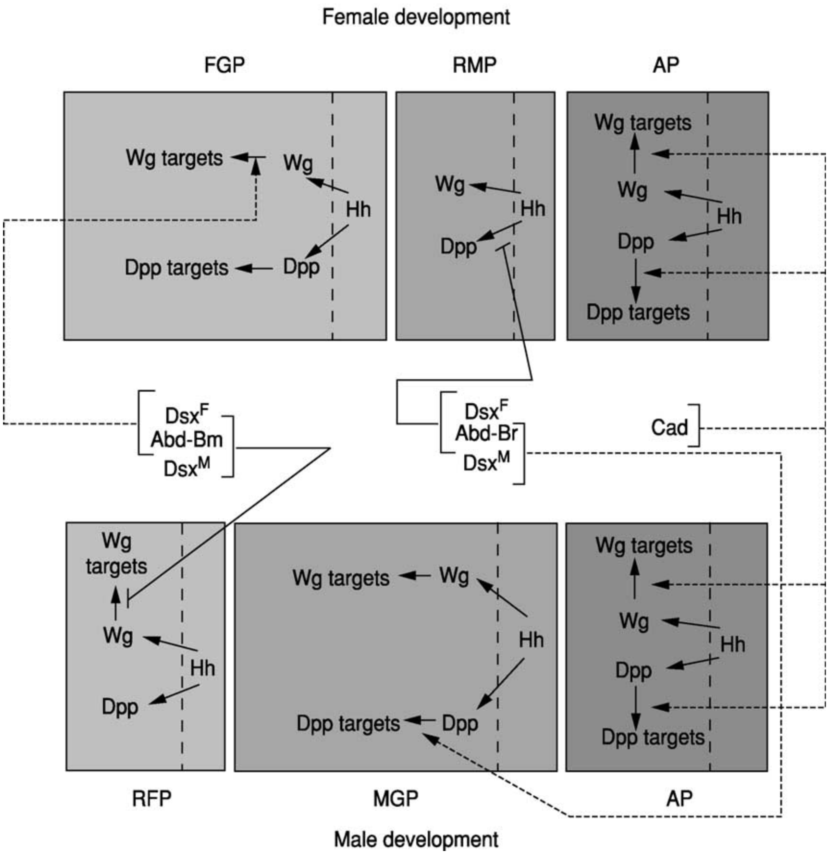

Figure 13 Schematic representation of the control of dimorphic sexual development of male and female genital primordia by the *dsx*, *Abd-B*, and *cad* genes. A8, A9, and A10–11 indicate the 8th and 9th abdominal segments, and the fusion of 10th and 11th abdominal segments, respectively. The repression of Dpp expression in the RMP and the repression of the Wg pathway in the RFP are indicated by a continuous line. The activation of Wg and Dpp pathways are indicated by stippled lines in the FGP and MGP, respectively. See text for explanation. The broken line represents the anteroposterior compartment border in each primordia.

(Gorfinkiel *et al*., 1997), the counteracting effect of Abd-B would be required to avoid leg development in the genitalia, and the *Dll* regulatory region would integrate the activating and repressing signals to control *Dll* transcription (Estrada and Sánchez-Herrero, 2001).

The *cad* gene (**Figure 13**) is expressed in the anal primordium and gives rise to two different structures: the hindgut and the anal plates. This gene is required for the development of anal structures and, when ectopically expressed, can induce ectopic analia (Moreno and Morata, 1999). Because of this and despite the fact that *cad* is not physically linked to the Hox cluster, it is the fly's most posterior Hox gene (Moreno and Morata, 1999). Consistently, *cad* clones show ectopic expression of *Abd-B* and concomitant transformation to genital structures in males (Moreno and Morata, 1999). Cad also activates *Dll* in the anal primordium; *brachyenteron* (*byn*), which is required for the development of the larval hindgut (Wu and Lengyel, 1998); and *even-skipped* (*eve*), another homeobox gene that is expressed in the presumptive region of the hindgut but is not required for hindgut development. *Dll* is also activated in the anal primordium by the combined action of Wg and Dpp, and is required for the formation of the anal plates (Gorfinkiel *et al*., 1999). Curiously, a mutually repressive interaction exists between *Dll* and *eve* in the anal primordium (Gorfinkiel *et al*., 1999).

Thus, in the anal primordium, Cad acts in combination with Wg and Dpp to activate *Dll* (Moreno and Morata, 1999), while in the genital primordia, the Hox gene *Abd-B* counteracts the Wg and Dpp signals in order to downregulate *Dll* (Estrada and Sánchez-Herrero, 2001) (see Section 1.1.2.3.4) (**Figure 13**).

1.1.2.3.4. Do the analia show a complex organization? Two chitinous plates, one dorsal and the other ventral to the anal opening, form the female analia. Two chitionous plates also form the male analia, one to the right and the other to the left of the anal opening (**Figure 8**). As mentioned above, the male and female analia behave as homologous structures derived from a common population of cells. Some experimental results, however, support the notion that the analia of both sexes may be derived from two distinct primordia, one giving rise to the dorsal analia in females or the complete analia in males (homologous primordium), while the other produces the ventral analia in females and no structure in males (nonhomologous primordium) (Andersen, 1979). A similar relationship has been described for the male and female analia in *D. virilis* (Newby, 1942).

First, XX;*dsx*^{D}/+, XX;*dsx*/*dsx*, or XX;*ix*/*ix* intersexes show one large horseshoe-shaped anal plate or separated left and right drop-shaped lobes, and a rudimentary plate with only two long bristles located ventral to the large plate (Andersen, 1979). Second, diplo-X homozygous *tra-2*^{ts} animals reared at 21 °C (intermediate temperature between female- and male-determining temperature) develop a dorsal anal plate with the appearance of dorsally fused right and left male anal plates, while the ventral anal plate is greatly reduced or absent (Belote and Baker, 1982).

Third, various degrees of sexual transformation in the analia were exhibited by diplo-X homozygous *tra-2*^{ts} animals reared at temperatures intermediate between 16 and 29 °C, or in animals that were shifted from 29 to 16 °C at progressively later stages of larval development. With increasing degrees of masculinization (progressively later shifts), the ventral female anal plate becomes reduced, while the dorsal plate changes into the horseshoe-shaped form that was described above for intersexual flies, becoming split into a left and right plate in the most extreme transformation (Epper and Bryant, 1983). Fourth, the shift of XX; *tra-2*^{ts}/*tra-2*^{ts} animals from 16 to 29 °C resulted in the quick formation of pure male anal plates. In the opposite shift, however, the formation of pure female anal plates occurred gradually. Moreover, the time course, required for the dorsal and ventral anal plates to show normal female phenotype, was different: when the dorsal anal plates were completely normal, it was still possible to find incomplete ventral anal plates (Sánchez and Granadino, 1992). Finally, in flies mutant for *Dll* alleles with different degrees of functionality, the dorsal female anal plate and the two male anal plates are reduced, whereas the ventral female anal plate is normal. Furthermore, *Dll*$^{-}$ clones do not develop anal plates in males or dorsal anal plates in females, but the development of the ventral female anal plates is not affected (Gorfinkiel *et al*., 1999). Thus, the dorsal female and male anal plates show the same genetic requirement for their development, supporting the idea that both are derived from a common primordium. It remains unknown, however, whether the segmental origin of this primordium is A10, and whether that of the ventral female analia forming primordium is A11.

1.1.2.3.5. Interaction between genital disc primordia The working model that emerges for the development of the genital disc is that each primordium develops as an independent unit in response to the general genetic cues that are also valid for other types of discs. However, there are also some results

suggesting that the development of one primordium affects the development of the others.

First, the regeneration of the genital disc, when different fragments of it are mixed (Littlefield and Bryant, 1979), suggests that some information is exchanged between primordia. Second, when cells of the anal or the genital primordia are killed by ectopic expression of the toxic *ricin A* gene, the development of the whole genital disc is impaired (Gorfinkiel *et al*., 2003). Similarly, mutations in *Abd-Br*, which is expressed only in A9 (see Section 1.1.2.4.4), produce a lack of female genitalia and analia (Casanova *et al*., 1986), and *Abd-B* mutations that transform the A8 and A9 segments into abdomen produce an absence of analia (Estrada and Sánchez-Herrero, 2001). Third, because the genital disc results from the fusion of three adjacent segments, the posterior compartment of one segment is contiguous with the anterior compartment of the corresponding segment and the anterior compartment of the following one. Thus, it has been found that Hh in the posterior compartment diffuses in both directions and induces different target genes for and aft. While *wg* and/or *dpp* are induced towards the anterior, *en* expression is induced towards the following segment. These results suggest that signals can diffuse across the different primordia of the genital disc (Gorfinkiel *et al*., 2003).

Accordingly, the ectopic expression of *hh*, *wg*, or *dpp* in the anal primordium induces duplications of genital structures. Also, *dpp* and *wg* mutant phenotypes that affect mainly the genitalia, can be rescued by expressing these genes in the analia. While the nonautonomous effect of Dpp is mediated by Dpp itself, the effect of Wg may be mediated by an as yet unidentified signal (Gorfinkiel *et al*., 2003).

In summary, it can be concluded that the development of the different primordia of the genital disc is interdependent and that specific signals may diffuse across the segmental boundaries.

1.1.2.4. Genetic Control of the Sexual Dimorphic Development of the Genital Disc

1.1.2.4.1. Interaction of sex determination genes with signaling pathways Sexual differentiation deeply affects patterning and growth of the genital disc, suggesting that sex influences not only the terminal differentiation genes but also the early events in the morphogenesis of the genital structures. Accordingly, the development of the male and female genital disc requires the integration of the information supplied by the sex determination gene *dsx*, the morphogenetic signaling pathways, and the Hox genes. How this integration of patterning genes and Dsx takes place is starting to be elucidated.

The RMP of the Dsx^F-containing female genital disc does not express *dpp* (Freeland and Kuhn, 1996; Casares *et al*., 1997) (**Figure 13**). The lack of *dpp* expression in the RMP cannot be attributed to the failure of cells to receive the Hh signal, because Hh induces expression of *wg* in these cells. Rather, the *dsx* gene renders the cells of the male genital primordium capable or incapable of activating *dpp*. The cells of the male genital primordium are able to activate *dpp* in response to the Hh signal in male (absence of Dsx^F) but not female (presence of Dsx^F) genital discs (**Figure 13**). Thus, clones mutant for *tra-2* (which is required for Dsx^F protein production) induced in the RMP of female genital discs, are always associated with *dpp* activation and show nonautonomous overgrowth (Sánchez *et al*., 2001).

Furthermore, it was also shown that the sex of the cells in the anterior compartment close to the anteroposterior compartment border (Hh responding cells), and not the sex of the whole genital disc, was the major factor controlling the growth of the genital primordia. When these cells are feminized in a male disc or masculinized in a female disc, both genital primordia respond by switching to growth patterns that reflect the sex in the induced anteroposterior compartment cells. Furthermore, these sexual changes in the Hh responding cells can change the expression of *dpp* in these cells (Keisman and Baker, 2001).

Collectively, these results indicate that the developing or repressed status of the male genital primordium may be controlled by Dsx at the level of *dpp* expression, thereby dictating the sex specific patterns of growth within the genital disc (Keisman and Baker, 2001; Sánchez *et al*., 2001). Moreover, it has been shown that Dsx^F is continuously required during female larval development to prevent activation of *dpp* in the RMP (Sánchez *et al*., 2001) (see Section 1.1.2.4.2).

The low proliferation rate of RFP in male genital discs cannot be attributed to the lack of Dpp or Wg, since both genes are expressed. Neither can it be due to a failure to respond to the Dpp signal, because the RFP expresses the Dpp-target gene *omb* (Gorfinkiel *et al*., 1999). Moreover, *Dll*, a Wg and Dpp target gene in the genital disc (Gorfinkiel *et al*., 1999), is not expressed in the RFP, where there is Dsx^M product, but is induced in the growing female genital primordium of genital discs that lack Dsx^M (Sánchez *et al*., 2001). Thus, the repressed status of the female genital primordium seems to be controlled by blockage of the Wg signaling pathway by Dsx^M. Moreover, it has been also observed that Dsx^M is not continuously required during larval

development for blocking the Wg-signaling pathway in the FGP (Sánchez *et al.*, 2001) (see Section 1.1.2.4.2).

The sex determination genes also control the fibroblast growth factor (FGF) signaling cascade. The *branchless* (*bnl*) and the *breathless* (*btl*) genes, which encode FGF and its receptor, respectively, in *Drosophila*, are each expressed in two bilaterally symmetrical and adjacent groups of cells in the mature male but not female genital disc (Ahmad and Baker, 2002). The *btl*-expressing cells give rise to paragonia and *vas deferens*, which are major parts of the internal male genitalia (**Figure 8**). The induction of ectopic Tra^{+} clones in the MGP of the male genital disc represses *bnl* expression. Conversely, in *dsx* mutant discs, where neither Dsx^{F} nor Dsx^{M} proteins are present, Bnl is expressed in the A8 and A9 segments. This indicates that Dsx^{F} represses the FGF pathway in the female genital disc and maybe Dsx^{M} activates this pathway in males (Ahmad and Baker, 2002).

1.1.2.4.2. The Dsx^{M} and Dsx^{F} products play positive and negative roles in the development of both the male and female genital primordia The established model for the development of the genital disc states that the male and female genital primordia, which are derived from two different cell populations, develop normally unless Dsx^{F} and Dsx^{M}, respectively, repress them (review: Steinmann-Zwicky *et al.*, 1990). Accordingly, these two proteins play a negative, rather than positive, role in the developmental control of the genital disc. This model is primarily based on the observation that intersexual *dsx* mutant flies – simultaneously lacking Dsx^{M} and Dsx^{F} proteins – develop both male and female adult genital structures. These male and female genital structures are derived from the male and female genital primordia, respectively (recall that in these intersexual flies both the male and female genital primordia develop) (see Section 1.1.2.4.1). However, the inventory of these structures is not complete. This cannot be attributed to the mutual interference of male and female genital primordia, which develop simultaneously, because gynandromorphs (flies in which X0 male and XX female cells are observed within the same individual) with complete male and female adult genitalia have been found (Nöthiger *et al.*, 1977). Rather, it seems that in the *dsx* intersexual condition, both the male and female genital primordia fail to develop completely. Indeed, the number of cells in the mature *dsx* intersexual genital disc does not add up to the complete male plus female genital disc complement (Ehrensperger, 1983). This suggests that in the absence of Dsx^{M} and Dsx^{F} products, both male and female genital primordia proliferate, albeit incompletely, and points to a positive role for Dsx^{M} and Dsx^{F} in the development of male and female genital primordia, respectively.

Recent results concerning the expression of the gene *dachshund* (*dac*) in the genital disc (Sánchez *et al.*, 2001) support the standard model but also raise some uncertainties including one related to the positive role of the Dsx products in the development of the genital disc. In normal female genital discs, which have the Dsx^{F} product (**Figure 13**), *dac* is expressed in the Wg but not in the Dpp domain. In normal male genital discs, which have the Dsx^{M} product (**Figure 13**), *dac* is expressed in the Dpp but not in the Wg domain (Keisman and Baker, 2001; Sánchez *et al.*, 2001). In genital discs simultaneously lacking or having both Dsx^{M} and Dsx^{F} products, *dac* shows low levels of expression in both the Wg and Dpp domains. This agrees with the idea that *dac* is regulated by Wg in the female genital disc and by Dpp in the male genital disc, and that this differential regulation requires the function of *dsx*. This is also compatible with the idea that Dsx^{M} and Dsx^{F} have dual roles with respect to the expression of *dac* in the genital disc. In male genital discs, Dsx^{M} positively and negatively regulates *dac* expression in the Dpp and Wg domains, respectively. In female genital discs, Dsx^{F} positively and negatively regulates *dac* expression in the Wg and Dpp domains, respectively.

At another level, Dsx has been also found to have an instructive and restrictive function. It was recently found that both the male and female primordia give rise to part of the adult structures in both sexes (Keisman and Baker, 2001). Using the expression patterns of genes such as *en* or *wg* as markers to track different genital primordia during metamorphosis, it was shown that each primordium gives rise to specific structures in each sex. In females, the male primordium forms a pair of female-specific accessory glands, whereas in males it produces a miniature eighth tergite. These findings indicate that, in one case, Dsx directs the female genital primordium to form either female genitalia or eighth tergite, and the male genital primordium to produce either male genitalia or the parovaria.

Such a dual role of the Dsx products is not unique to the genital disc. A similar role has been observed in the regulation of the female-specific *yolk protein* (*yp*) genes: Dsx^{M} represses the *yp* genes in males, whereas Dsx^{F} activates the *yp* genes in females (see **Chapters 1.2** and **1.3**). In flies that lack both Dsx products, the *yp* genes are expressed at a basal level (Bownes and Nöthiger, 1981; Coschigano and

Wensink 1993; Waterbury *et al*., 1999). A positive role for Dsx^M has been also observed in the development of the sex comb in males (Jurnish and Burtis, 1993).

1.1.2.4.3. Different time requirements for the Dsx^M and Dsx^F products The following set of results suggests that the development of male and female genital primordia has different time requirements for Dsx^M and Dsx^F products:

1. Analysis of the growth of genital primordia and their capacity to differentiate adult structures in homozygous *tra-2^ts^* genital discs with two X chromosomes was performed using pulses of the male- and the female-determining temperatures in both directions during development. Regardless of the stage in development at which the female-determining temperature pulse was given (transient presence of functional $Tra\text{-}2^{ts}$ product, i.e., transient presence of Dsx^F product and absence of Dsx^M product), the male genital disc developed normal male adult genital structures and not female ones. This occurred even when the pulse was applied during pupation. Pulses at the male-determining temperature (temporal absence of functional $Tra\text{-}2^{tts}$ product, i.e., transient absence of Dsx^F product and presence of Dsx^M product), before the end of first larval stage produced female and not male genital structures. However, later pulses always gave rise to male genital structures, except when the pulses were given close to pupation. Further, the capacity of the female genital disc to differentiate adult genital structures was also reduced when the temperature pulse was applied during metamorphosis (Sánchez *et al*., 2001).
2. When the effect of the male-determining temperature pulses was analyzed in the genital disc, it was found that overgrowth of the RMP was always associated with the activation of *dpp* in this primordium. However, this activation and the associated overgrowth only occurred when the temperature pulse was given after the end of first larval instar. This suggests that there is a time requirement for induction of *dpp*. The activation of this gene in the RMP and the cell proliferation that resumed in this primordium, as well as its capacity to differentiate into adult structures, was irreversible, since these were maintained upon return of the larvae to the female-determining temperature, when functional $Tra\text{-}2^{ts}$ product (i.e., presence of Dsx^F product and absence of Dsx^M product) was again available (Sánchez *et al*., 2001).
3. The conclusion for the time requirement for induction of *dpp* was also supported by the fact that dsx^{11} clones (which lack Dsx^M) induced in the developing male genital primordium of XY; dsx^{11}/+ male genital discs (which express only Dsx^M) after 24 h of development, differentiated normal male adult genital structures. However, when the dsx^{11} clones were induced in the time period between 0 and 24 h of development, they did not differentiate normally and gave rise to incomplete adult male genital structures.

   The different developmental capacity shown by the dsx^{11} clones depending on their induction time was explained as follows. When the clones were induced after 24 h of development, *dpp* was already activated. Indeed, these clones showed no change in the expression pattern of *dpp* or its targets (Sánchez *et al*., 2001). Accordingly, these clones displayed normal proliferation and capacity to differentiate male adult genital structures. On the contrary, when the clones were induced early in development, *dpp* was not yet activated, as this gene is not expressed in the male genital primordium of male genital discs early in development (Casares *et al*., 1997). Therefore, when the male genital disc reaches the state in development when *dpp* is induced, the cells that form the clones activate this gene as in *dsx* mutant intersexual flies, because the clones have neither Dsx^M nor Dsx^F products. Consequently, these clones do not achieve a normal proliferation rate and do not produce normal adult male genital structures (Sánchez *et al*., 2001).
4. The expression of the *dac* gene was analyzed in genital discs of diplo-X homozygous *tra-2^ts^* flies using pulses of the male- and the female-determining temperatures in both directions (recall that in male genital discs, Dsx^M positively and negatively regulates *dac* expression in the Dpp and Wg domains, respectively; and in female genital discs, Dsx^F positively and negatively regulates *dac* expression in the Wg and Dpp domains, respectively). It was found that the *dac* expression pattern switched from a “female type” to a “male type,” when male-determining temperature pulses were applied to *tra-2^ts^* larvae after the first larval instar. However, when the pulse was given during the first larval instar, *dac* was not activated in the Dpp domain of RMP, in spite of the fact that there was also a transient presence of Dsx^M instead of Dsx^F (Sánchez *et al*., 2001). This was explained by the lack of competence of cells to express Dpp, which is acquired after the first larval instar (Casares *et al*., 1997).

When the *tra-2*^{ts} larvae reach such a developmental stage, these cells produce Dsx^F because they are returned to the female-determining temperature. Dsx^F prevents activation of *dpp* in the RMP and, consequently, no induction of *dac* expression occurs. In the female genital primordium, *dac* expression is strongly reduced in the Wg domain and is absent from the Dpp domain.

Taken together, these results suggest that the development of male and female genital primordia have different time requirements for the Dsx^F and Dsx^M products. In females, Dsx^F is continuously required during female larval development for preventing activation of *dpp* in the RMP and, during pupation, for female cytodifferentiation. In males, Dsx^M seems not to be continuously required during larval development for blocking the Wg signaling pathway in the female genital primordium nor during pupation for male cytodifferentiation.

1.1.2.4.4. Integration of signaling pathways, sex determination, and homeotic information Homeotic and sex determination genes have to interact, along with the Hh, Dpp, and Wg signals, for normal development of the genitalia to occur (Keisman and Baker, 2001; Sánchez *et al*., 2001). The *dsx* gene controls which of the two genital primordia will develop and which one will be repressed. Nevertheless, since Dsx^M and Dsx^F are equally active in each cell of the A8 and A9 segments of the male and female, respectively, another gene(s) is required to distinguish between female and male genitalia. The female genitalia develop from the A8 segment and the male from A9 (Freeland and Kuhn, 1996; Casares *et al*., 1997). Since the *Abdominal-B* (*Abd-B*) gene is responsible for the specification of these posterior segments (review: Duncan, 1996) (see **Chapter 1.8**), it has been proposed that Abd-Br and Abd-Bm participate, together with *dsx*, in the sexually dimorphic development of the genital disc (Sánchez *et al*., 1997, 2001).

The genetic model that has been proposed for the control of the sexually dimorphic development of the genital disc (**Figure 13**), suggests that Dsx^M and Dsx^F combine with Abd-Bm and Abd-Br to make up the determining signals (Sánchez *et al*., 2001). First, it has been reported that Abd-B reduces the response to Wg and Dpp signals in the genital disc (Estrada and Sánchez-Herrero, 2001). Abd-B seems to repress *dac* and *Dll* expression (perhaps by antagonizing the Dpp and Wg signaling) in some cells of the male and female primordia. It is still unknown if this multiple input acts directly on the *dac* and *Dll* regulatory regions. Second, in the absence of both Dsx^M and Dsx^F products, there is basal expression of *dpp* and a basal functional level of the Wg signaling pathway in both the male and female genital primordia. This leads to both genital primordia developing, albeit incompletely. In normal females, the concerted input of Dsx^F and Abd-Br causes repression of the development of the male genital primordium by preventing the expression of *dpp* and resulting in the RMP of female genital discs. In normal males, the concerted input of Dsx^M and Abd-Bm represses the female genital primordium by blocking the Wg signaling pathway, which gives rise to the RFP of the male genital discs. It is further proposed that Dsx^M plus Abd-Br increase *dpp* expression and the response to the Dpp signaling pathway in the MGP of male genital discs, and that Dsx^F plus Abd-Bm enhance the Wg signaling pathway function in the FGP of female genital discs. Therefore, Dsx^M plays a positive and a negative role in male and female genital primordia, respectively, while Dsx^F plays a positive and a negative role in female and male genital primordia, respectively.

Such integration of the *dsx* and *Abd-B* functions seems not to be exclusive to the genital disc. The *Drosophila* 5th and 6th abdominal tergites are formed in both sexes, but in females they show dark pigmentation restricted to the posterior region (non-sex-specific pigmentation), whereas in males the pigmentation covers the whole tergite. The gene *bric-a-brac* (*bab*) is involved in the sexually dimorphic pigmentation of these tergites by integrating regulatory inputs from *dsx* and *Abd-B* (Kopp *et al*., 2000). Another integrated genetic input made up by *dsx* and the homeotic gene *Sex combs reduced* (*Scr*) has been invoked for sex-specific differentiation of the basitarsus of the prothoracic leg (see **Chapter 1.9**). This contains the sex comb, another male-specific structure (Jurnish and Burtis, 1993). However, it is not known at which level this interaction takes place.

1.1.2.5. Gradual Acquisition of the Developmental Capacity to Differentiate Adult Structures

At the end of the larval period, each mature imaginal disc represents a set of cells with different determination states that will be realized (differentiation) during metamorphosis as a response to the hormonal stimulus (ecdysone), resulting in the adult pattern that characterizes each imaginal disc (Nöthiger, 1972). It has been reported, however, that imaginal discs acquire their capacity to differentiate into adult structures gradually throughout their larval growth; i.e., there is a specific temporal sequence in which the structures from imaginal discs

of increasing age differentiate, this sequence being unique for each disc. These temporal sequences have been reported for the imaginal discs of the leg (Schubiger, 1974), the eye–antenna (Mindek and Nöthiger, 1973; Gateff and Schneiderman, 1975), and the wing (Bownes and Roberts, 1979) (see **Chapter 1.9**). This was determined through transplantation of imaginal discs, from larvae at different stages of development, into mature larvae ready to pupate, and analyses of the inventories of adult structures derived from the implanted discs upon eclosion.

The genital disc also shows a gradual acquisition of the developmental capacity to differentiate adult structures. The strategy used for the demonstration of the latter (Sánchez and Granadino, 1992) involved a temperature-sensitive allele *tra-2^{ts1}* that was characterized because XX flies homozygous for this mutation develop as females at the permissive temperature (16 °C), whereas they develop as males at the restrictive temperature (29 °C) (Belote and Baker, 1982) (see Section 1.1.2.4.3 for the function of gene *tra-2*). The rationale of the strategy was as follows. When *tra-2^{ts1}* homozygous diplo-X larvae are raised at 16 °C, when the Tra-2 product is active, the FGP develops while the development of the MGP is blocked. If, during larval development, these larvae are shifted to 29 °C, when no functional Tra-2 product will be available, the cells of the MGP will enter into a normal proliferation rate (Belote and Baker, 1982; Epper and Bryant, 1983). The degree of growth that the MGP reaches will depend on the time during development when the temperature shift is performed. Therefore, it is possible to establish a correlation between the development attained by the MGP and its capacity to differentiate adult structures. At the same time that the shift from 16 to 29 °C prompts the MGP to develop, the cells of the FGP, which are developing at a normal rate, are brought into the slow proliferation rate that characterizes the RFP of the male genital disc, as a consequence of the inactivation of the Tra-2 product at the high temperature. Hence, it is possible to asses the developmental capacity attained by the FGP for differentiation of adult structures, when its normal growth is blocked at certain times before metamorphosis. An analogous situation occurs when the temperature shift goes from the 29 to 16 °C but, in this case, the behavior of the female and male genital primordia is reversed.

The results showed that the male genital primordium (male genital disc) follows a temporal sequence in its capacity to differentiate male external adult structures: the genital arch and lateral plates were the first structures that the male genital primordium differentiated, followed by the clasper, hypandrium, and penis apparatus (see **Figure 8** for the structures). Also, the female genital primordium (female genital disc) exhibits a sequence of capacity to differentiate external adult structures (8th tergite before vaginal plate), although in this case it is difficult to define a clear-cut sequence due to the reduced morphological elements that form the external adult female genital pattern. With respect to the analia, where cells proliferate independently of the state of *tra-2* activity (Belote and Baker, 1982; Epper and Bryant, 1983), the temperature shift between 16 and 29 °C, in both directions, indicated that the anal cells show a plasticity to change their sexual developmental program. Nevertheless, the change from female to male development occurred quickly, whereas that from male to female occurred gradually (Sánchez and Granadino, 1992).

There is a correlation between the sequence of structures differentiated by the genital disc and their topography in the fate map of the mature genital disc (Littlefield and Bryant, 1979; Ehrensperger, 1983; Epper and Bryant, 1983), as well as their cell lineage relationship (Dübendorfer and Nöthiger, 1982). It was suggested that this sequence is related to the dynamics of growth of the genital disc. It was further suggested that, at the end of the larval period, the mature genital disc is a mosaic of cells with different states of determination which, through metamorphosis, will differentiate into the distinct adult structures that form the terminalia. This mosaic pattern of the mature genital disc is not attained as an all-or-nothing event at the end of the larval period. Rather, during larval development, the proliferating genital disc is a mixture of cells already determined and cells that are still on their way to acquire a state of determination. The temporal sequence in the capacity to differentiate adult structures would reflect the temporal sequence of determination events in the genital primordia.

In the temperature shift experiments of XX; *tra-2^{ts}/tra-2^{ts}* animals, duplicated male genital structures corresponding to the penis apparatus were found. A similar duplication is observed in *dsx* or *dsx^{D}* intersexual flies (Epper, 1981). What is the origin of these duplicated structures? The remaining vaginal plates always enclose the secondary set of male genitalia, whenever these female structures are formed. This location suggests that the duplicated male structures derive from the female genital primordium. Several results support this interpretation. Fate mapping of the *dsx^{D}* intersexual genital discs showed that the small penis duplication maps on the female genital primordium (Epper, 1981). Moreover, Epper and Bryant (1983), in their experiments

of culturing *in vivo*, at the male-determining temperature, fragments of XX; *tra-2^ts^/tra-2^ts^* genital discs that had been developing at the female-determining temperature, observed that the female genital fragment differentiated small penis structures.

It is possible to argue that cutting errors during disc sectioning are the cause for the presence of the duplicated male structure. However, an independent observation supporting the notion that the penis duplication originates from the female genital primordium, stems from the analysis of the effect of *en* alleles in the genital disc (Epper and Sánchez, 1983). The en^1/en^2 combination affects the female genital primordium, more severely, while the male genital primordium is most affected by the en^2/en^3 combination. In intersexual en^2/en^3; $dsx^D/+$ flies, despite the lack of the entire penis apparatus in the male genital set, the small duplicated penis is always present. This rudimentary duplication, however, is absent from intersexual en^1/en^2; *dsx/dsx* flies, while the penis of the male genital set is always present. Thus, the secondary penis seems to be recognized by the *en* combinations as an element of the female genital primordium. Finally, in the above mentioned cases, the duplicated male structure is always accompanied by a reduction in the size of the ventral region of the vaginal plates. Collectively, these results suggest that a group of cells from the female genital primordium have the potential of following two alternative sexual pathways. In wild-type females, this group of cells gives rise to the ventral region of the vaginal plate, while in wild-type males it forms part of the "repressed" RMP primordium. In intersexual flies, when both female and male genital primordia develop, this group of cells produces the secondary penis.

1.1.2.6. Evolutionary Considerations

Evolutionary changes in morphology do not necessarily involve the generation of novel cell types but rather changes in morphogenesis, i.e., in the processes that are responsible for the generation of three-dimensional arrangements of various cell types (Raff and Kauffman, 1983). What is the genetic basis for morphological evolution? The genital disc, in addition to being a good experimental model in which to examine the control of pattern formation, is also well suited for the study of morphological evolution. In this respect, two aspects of the genital disc can be highlighted. First, the female external terminalia are very similar in the *Drosophila* species. The external male terminalia, however, display great differences; indeed, these are some of the main features used in taxonomy (Tsacas and Bocquet, 1976). Therefore, the terminalia are particularly well suited for studying the great morphological variety observed in the male genitalia. The second aspect is related to the origin of the genital disc.

1.1.2.6.1. The genital disc in interspecific hybrids

The genetic basis for the morphological evolution of the genital disc has been addressed through the analysis of interspecific hybrids of *Drosophila*. This analysis has focused on the effect of quantitative trait loci (QTL) on the shape of a particular structure of the male terminalia, the lateral lobe, in the sibling species *D. melanogaster, D. simulans*, *D. mauritiana*, *D. sechellia*, and their hybrids (Coyne, 1983; Coyne *et al*., 1991; Liu *et al*., 1996). The morphology of the lateral lobe differs markedly in these species. The genetic basis underlying the formation of this structure was studied through the production of first generation-interspecific hybrids. In the cases where the female hybrids were fertile, F_2 backcrosses to males of either generation could be performed and it was possible to analyze hybrids that contained different combinations of genes of the two parental species. Evidence was presented supporting a polygenic basis for the shape of this male structure.

Analysis of the morphological variation in other interspecific hybrids cannot be carried out because, in the majority of the cases, the species never interbreed, due to ethological isolation or other causes. A way of circumventing this problem is to cross-transplant germ cells. If the germ cells from the donor can develop in the soma of a host, it may be possible to obtain interspecific hybrids when the chimeric adult hosts are mated with individuals of their own species (Santamaria, 1977; Sánchez and Schmid, 1984; Schmid *et al*., 1984; Lawrence *et al*., 1993). Following this strategy, germ cells from *D. yakuba* or *D. teissieri* – both belonging to the *melanogaster* subgroup (Lachaise *et al*., 1988) and not breeding with *D. melanogaster* – were transplanted into *D. melanogaster* host embryos, and the chimeric hosts were mated to *D. melanogaster* males. The germ cells of both donor species were capable of producing functional *yakuba* or *teissieri* oocytes, respectively, which, when fertilized by the *melanogaster* sperm, gave rise to *yakuba–melanogaster* and *teissieri–melanogaster* adult hybrids, whose external terminalia were characterized (Sánchez and Santamaria, 1997).

The female external terminalia are very similar in the three species, *D. melanogaster*, *D. yakuba*, and *D. teissieri*. The external male terminalia, however, display significant differences (Tsacas and Bocquet, 1976). The morphological differences in

the external terminalia of *yakuba–melanogaster* and *teissieri–melanogaster* male hybrids, and those of their parental species, can be either qualitative or quantitative and could be ascribed to four main categories:

1. There were structures in the three species that showed a different shape in their hybrids; for example, the edeagus, the hypandrium, and the lateral lobe.
2. There were structures that in the hybrids showed the morphology of one of the parental species; for example, the dorsal parameters in *teissieri–melanogaster* resembled those of *D. teissieri*.
3. There were structures present in the hybrids and in only one of the parental species; e.g., the penis mantle is absent in *D. teissieri* and present in *D. melanogaster* and in *teissieri–melanogaster* hybrids.
4. There were structures absent in the hybrids but present in the two parental species; e.g., the ventral parameres are present in *D. melanogaster* and *D. teissieri* but absent in their hybrids.

It was speculated that these morphological differences correspond to changes in two basic genetic mechanisms that control the generation of morphological patterns. Qualitative differences, which refer to the presence of absence of a given structure of the pattern, probably reflect a simple genetic basis, in which a single gene is at work (or a combination of a few genes, each contributing a qualitative effect). Quantitative differences, however, are also characterized, because the structures display more or less continuous variation or intermediate phenotypes, suggesting that a polygenic system is at work (each gene in the system has a minor effect and shows additivity) (Sánchez and Santamaria, 1997).

The *dsx* gene is the last gene in the sex determination cascade (**Figure 4**). The dsx^D mutation transforms females into intersexes while having no effect in males (Gowen, 1942; Denell and Jackson, 1972). The XX; dsx^D/+ intersexual flies contain both the Dsx^M (from the dsx^D allele) and Dsx^F (from the dsx^+ allele) products (Nagoshi and Baker, 1990). The dsx^D allele was introduced into the *teissieri–melanogaster* hybrids via *D. melanogaster* males crossed to chimeric *D. melanogaster* females carrying exclusively *D. teissieri* germ cells (Sánchez and Santamaria, 1997). The most conspicuous feature of the intersexual terminalia of XX; dsx^D/+ *D. melanogaster* flies is the presence of both male and female genital structures. These are reduced and arranged in two separate genitalia. Some intersexes show a reduction of genital structures to such an extent that only traces of male and/or female genitalia are present. The anal plates are always present and their shape resembles neither the wild-type male nor the normal female. Rather they display an intermediate sexual phenotype (Gowen, 1942; Denell and Jackson, 1972; Epper, 1981). The most salient characteristic of the intersexual terminalia of XX; dsx^D/+ *teissieri–melanogaster* hybrids was the great difference in the inventories of male versus female genital structures: in general terms, the external genitalia of these hybrids could be defined as male-like more than intersexual. There was an almost completely normal set of male genital structures. The analia, however, were intersexual (Sánchez and Santamaria, 1997).

As mentioned earlier, the *dsx* gene must act in concert with another regulatory gene(s) to determine the genital primordia that will develop in each sex. It has been proposed that this additional gene is *Abdominal-B* (*Abd-B*) (Sánchez *et al*., 1997, 2001). To explain the male-like phentoype of the genitalia of XX; dsx^D/+ *teissieri–melanogaster* hybrids, it was speculated that during the evolution of the *D. melanogaster* and *D. teissieri* species, genetic changes have occurred in the regulatory genes, such as *dsx* and/or *Abd-B*, and/or in the genes controlled by these regulators, which are responsible for the development of the terminalia (Sánchez and Santamaria, 1997). These species-specific variations could be responsible for the morphological changes observed in the terminalia of these species. When the genotypes of the two species are put together within a single hybrid cell, divergent coadapted gene complexes are confronted. This might result in the formation of hybrid patterns different from those of their parental species; i.e., in the production of morphological diversity.

1.1.2.6.2. The genital disc in other dipteran species The expression of pattern-forming genes in the genital disc indicates that this disc is organized like the ventral, leg, and antenna discs (see **Chapter 1.9**). Evolutionary studies have suggested that the terminalia arose as a modification of a primitive appendage of a common ancestor to all arthropods (Matsuda, 1976). It has also been suggested that *Dll* expression along the proximal–distal axis arose once in an appendage-bearing ancestor, and has been utilized repeatedly in body wall outgrowths ever since (Panganiban *et al*., 1997). It can be hypothesized that the *Abd-B* function has modified this "ground state" in order to allow genitalia differentiation. This modification appears to be concomitant with the tendency towards a reduction of the structures (through the fusion of corresponding segments)

posterior to the 5th abdominal segment. Such reductions have occurred to different extents in males and females, leading to an increase in sexual dimorphism (Crampton, 1942; Matsuda, 1976). Two major features characterize this evolution: a decrease in the number and size of posterior-most tergites and sternites, and the fusion of posterior segments into a single genital disc (Crampton, 1942; Matsuda, 1976).

Insects such as *Musca* (Dübendorfer, 1971) and *Calliphora* (Emmert 1972a, 1972b), which are more primitive than *Drosophila*, have two lateral and one median genital discs. The primordium of the lateral discs corresponds to A8, and that of the single median disc to the fusion of A9 to A11 (**Figure 14**). In females, the lateral discs form the female genitalia, except for the parovaria. The median disc forms the parovaria (A9) and the female analia (A10–A11). In males, the lateral discs produce a reduced eighth tergite. The median disc develops the male genitalia (A9) and the male analia (segments A10–A11) (**Figure 14**). A further level of fusion has occurred in the *Drosophila* lineage, where segments A8 to A11 form a single genital disc (**Figure 14**).

1.1.3. Concluding Remarks and Perspectives

Perpetuation by sexual reproduction is the rule within the animal kingdom. The sex determination mechanisms have long been of major interest from a developmental and evolutionary point of view. There is a plethora of mechanisms whereby formation of males and females occurs through a species' ontogeny. This is more evident in insects, where all types of sex determination mechanisms are represented.

The characterization of the genes that control sexual development in *Drosophila* contributed significantly to the understanding of the molecular strategies behind sex determination, sex behavior, and the development of the germline (see **Chapters 1.2** and **1.4**). This knowledge paved the way for the study of the sex-determination mechanisms in other insects, so that the understanding of evolution of the sex-determining mechanisms is now possible. This will undoubtedly also contribute to an increased understanding of the evolution of other genetic pathways. In addition, results from studies on the mechanisms that control sexual development, are likely to contribute to the development of novel

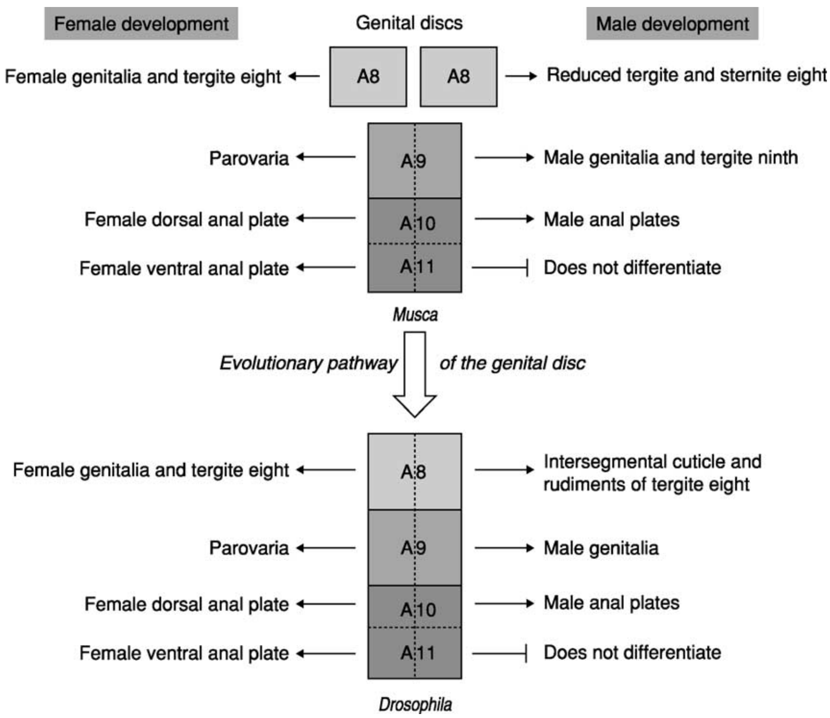

Figure 14 Hypothetical evolutionary pathway of the genital disc. Comparison of the genital discs of *Musca* (upper) and *Drosophila* (lower). A8–11 stands for abdominal segments 8–11. Strong experimental evidence supports the idea that the anal primordium of the *Drosophila* genital disc shows a complex organization (see text for explanation). Therefore, it is illustrated that two cell populations, assumed to be derived from segments A10 and A11, respectively, form the anal primordium (the horizontal broken line indicates the different segmental origin). It is further assumed that this organization is already present in *Musca*. The dotted line running from top to bottom indicates the bilateral symmetry organization of the genital disc.

strategies for the control or eradication of harmful insects that fhave a serious detrimental economic impact in agriculture and affect human health.

Traditionally, the control of pest insects has been performed by the use of insecticides. Although this strategy is quite effective, it has important disadvantages including the pollution of the environment, a significant risk for human health, and the appearance of insecticide resistance in the pest population. This is the reason why biological control of pest insects is receiving increasing attention. The biological control of insect pests has been carried out by the release of sterilized adults into the pest population, as is the case with the fruit flies. Although this method can be quite effective, there are certain aspects that are undesirable. Only the sterile males contribute positively to pest control, yet both males and females are mass-reared and released into the environment. Although females are sterile, they are undesirable because they can still cause crop damage through oviposition. Consequently, the selective elimination of females would be extremely important for biological control of insect pests. Two potential strategies can accomplish this goal. One of them is based on the selective expression, in females, of a harmful gene, which would be under the control of female-specific regulatory sequences. The second strategy is based on the transformation of females into sterile males or intersexes lacking the ovipositor structure, due to the expression of a gene that causes male instead of female development. Both strategies require the isolation and further characterization of the genes controlling sex determination and/or sex-specific regulatory sequences, as well as the development of vectors (transposable elements) that would allow the formation of transgenic fruit flies (see also **Chapters 4.12**, **4.13**, and **5.12**).

Drosophila has a single genital disc that produces the terminalia, the most sexually dimorphic structure in the adult. The founder cells are recruited from different segments to form the two genital primordia, female and male, plus the anal primordium that constitute the genital disc. In addition to being a good experimental model for the study of the control of pattern formation, the genital disc is also well suited for the study of morphological evolution. In this respect, two aspects of the genital disc can be highlighted. First, the fact that the female external terminalia are very similar in the *Drosophila* species. The external male terminalia, however, display great differences. Therefore, the terminalia are a good experimental model for understanding the mechanisms controlling morphogenesis. In addition, they are particularly well suited for studying the causes determining the relative morphological simplicity observed in the female genitalia, and the great morphological variety observed in the male genitalia. The second aspect is related to the origin of the genital disc. The expression of pattern-forming genes in the genital disc supports the idea that the terminalia arose as the result of the modification of a primitive appendage of a common ancestor to all arthropods. This modification appears to be concomitant with the tendency towards the reduction of structures (through the fusion of corresponding segments) posterior to segment A5. Such reductions have occurred to different extents in males and females, leading to an increase in sexual dimorphism. The knowledge acquired from the study of the *Drosophila* genital disc allows us to address questions about the organization and development of the genital disc in other insects. This will aid us to understand the evolution of the genital disc and, ultimately, morphological evolution.

1.2 Oogenesis

D A Dansereau and P Lasko,
McGill University, Montreal, QC, Canada
D McKearin, University of Texas,
Dallas, TX, USA

1.2.1. Introduction

Drosophila have polytrophic ovarioles: each oocyte develops in an egg chamber (follicle), containing a cluster of interconnected germline cells (cyst) surrounded by a layer of mesodermal follicle cells. In principle, whatever applies to *Drosophila* also broadly applies to many other insects with polytrophic ovarioles (e.g., *Anopheles* and *Bombyx*; see also **Chapter 1.3**).

The *Drosophila* oocyte develops within a cyst of 16 interconnected germline cells, all derived from one cystoblast through mitotic divisions. Egg chambers are assembled in the germarium, a mitotically active zone at the anterior tip of each ovariole. Here, mitotic division of a germline stem cell (GSC) renews the GSC and produces a cystoblast, which undergoes four synchronous mitotic divisions to generate a 16-cell cyst (Figure 1). Cystocyte cell cycles are rapid and uncoupled from cell growth, leading to a progressive reduction in cell volume. Older cysts migrate posteriorly through the germarium, and are individually surrounded by mesodermal follicle cells, thus forming egg chambers. Follicle cell migration is associated with the flattening and lengthening of the cyst perpendicular to the anterior–posterior (A–P) axis so that it spans the width of the germarium.

Each germarium, which can be further subdivided into four consecutive and morphologically and functionally distinct regions (1, 2A, 2B, and 3; Figure 2), typically contains 7–12 developing 16-cell cysts. There are 6–7 egg chambers per ovariole connected to each other by stalks of follicle cells (Figure 2). As

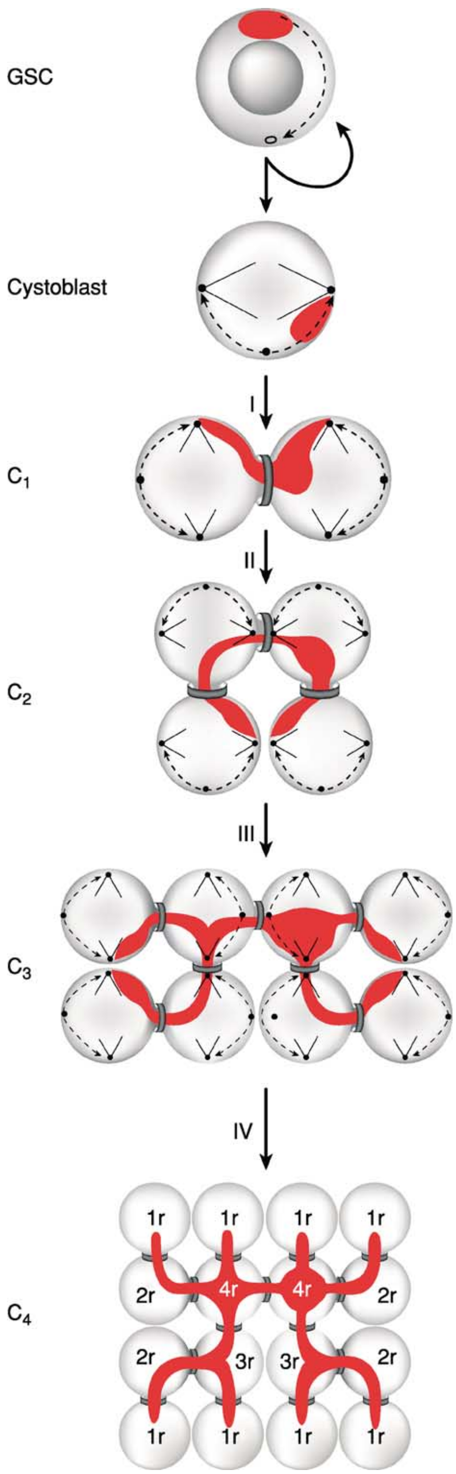

Figure 1 Cyst divisions in region 1 of the germarium. Oogenesis begins with the asymmetric division of a germline stem cell (GSC) at the anterior tip of germarial region 1. One daughter remains in the stem cell niche and is maintained as a GSC, while the second leaves the stem cell niche and differentiates as a cystoblast (discussed in Section 1.2.2). Each cystoblast divides four times (I–IV) with incomplete cytokinesis to give rise to a cyst of 16 cells connected to each other by cytoplasmic bridges called ring canals (discussed in Section 1.2.3). This leads to the production of a cyst containing only two cells with four ring canals (marked 4r), one of which becomes the oocyte and undergoes meiosis (discussed in Section 1.2.4.1). Broken arrows denote centriole migration and open arrowheads represent mitotic spindles. During these divisions, a membranous cytoplasmic organelle called the fusome, shown in red, anchors one pole of each mitotic spindle, orienting and synchronizing each cyst division (discussed in Sections 1.2.3.2 and 1.2.3.3). These organelles are spherical in GSCs, where they are called spectrosomes, but grow and fuse to become elongated, branched structures that extend through each ring canal during cyst divisions. The cystocyte that is chosen to become the oocyte might be determined as early as the first cystoblast division, when one daughter inherits more fusome than the other. This initial asymmetry is propagated through subsequent divisions and likely plays a central role in specifying oocyte fate (discussed in Section 1.2.3.2).

development proceeds, a rhythmically contracting muscular epithelial sheath pushes egg chambers progressively toward the posterior. Thus, each ovariole can be considered as a linear assembly line for the formation of eggs, with progressively older egg chambers toward the posterior. Seventeen to 20 discrete tubular ovarioles are packaged together in parallel, in each of the two ovaries. Each ovary is surrounded by a network of muscle fibers called the peritoneal sheath and both are connected to a common oviduct with associated accessory sex glands (see **Chapter 1.5**). As mature eggs pass from the common oviduct into the uterus, they are fertilized by sperm stored in the ventral receptacle and spermathecae. The germline-derived cell types are the GSCs and the cystocytes of individual egg chambers, which develop into nurse cells and the oocyte. Somatic tissue surrounding the egg chambers is derived from the gonadal mesoderm. All other structures of the reproductive system differentiate from the genital imaginal disc (see **Chapter 1.1**).

Oogenesis can been divided into 14 stages based on morphological criteria (King, 1970). Stage 1 refers to a newly formed egg chamber and stage 14 is a mature egg that is ready to be fertilized and oviposited. The mature egg is visibly asymmetric along its A–P and dorsal–ventral (D–V) axes (**Figure 2**). It has an anterior micropyle and anterior dorsal appendages, a posterior aeropyle, and is more curved on the ventral surface relative to the dorsal one. This polarity is defined and maintained during oogenesis through communication between the follicle cells and the developing nurse cell-oocyte complex.

1.2.2. Stem Cells

1.2.2.1. Germline Stem Cells and the Stem Cell Niche

Stem cells are defined by their ability to self-renew and produce daughters that differentiate. There are

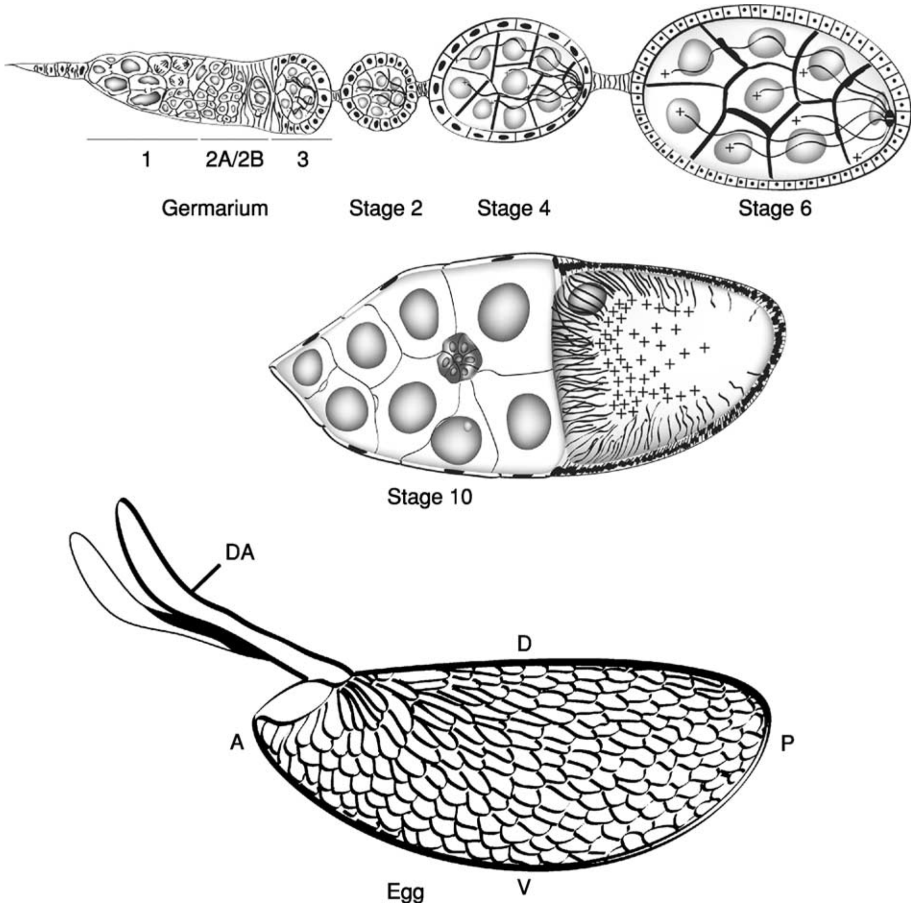

Figure 2 *Drosophila* ovarioles and egg chambers. *Drosophila* ovaries are organized into approximately 17 tubular structures called ovarioles that contain progressively maturing egg chambers. Different developmental stages from a single ovariole are pictured here. Egg chamber development initiates in the germarium at the anterior tip of each ovariole, which can be divided into three sections based on different stages of cyst development. Region 1 is filled with mitotically active cells: germline stem cells (GSCs), somatic stem cells (SSCs), and dividing cystocytes (Sections 1.2.2 and 1.2.3). In region 2, 16-cell cysts change shape to take up the width of the germarium, and the oocyte is determined (discussed in Section 1.2.2.4.1). Cysts are encapsulated by somatic follicle cells in region 2, and a subpopulation of follicle cells between adjacent cysts intercalates in region 3 to form a stalk, causing the newly formed stage 1 egg chamber to bud from the germarium (discussed in Section 1.2.5.1). Oogenesis can be further subdivided into 14 stages based on morphological criteria, where stage 1 refers to a newly formed egg chamber and stage 14 is a mature egg that is ready to be fertilized and oviposited. During stages 1–6, a stable microtubule organizing center (MTOC, marked with a black oval and minus sign in the stage 6 egg chamber pictured here) is present at the posterior of the oocyte (discussed in Section 1.2.4.1.1). It nucleates a single microtubule network (depicted as black lines) emanating through the ring canals into each nurse cell, with most MT minus ends focused in the oocyte. Until the cytoskeleton is reorganized during stages 6–7, mRNAs and proteins are steadily transported toward the MT minus ends, so that they accumulate in the oocyte. Major cytoskeletal reorganization occurs during stages 7–8, after which the posterior MTOC is no longer detected. A reorganized cytoskeleton emerges with the bulk of the MT network at the anterior, creating a higher density of MT in the anterior of the oocyte than the posterior. MT minus ends appear to be nucleated along the anterior and lateral cortices, with MT plus ends pointing into the center of the oocyte (discussed in Section 1.2.6.1 and portrayed in the stage 10 egg chamber drawn here). This cytoskeletal organization is required to direct the posterior localization of *osk* mRNA, the anterior localization of *bcd* mRNA, and the dorsal-anterior relocalization of the oocyte nucleus and *grk* mRNA. The mature egg (bottom drawing) is visibly asymmetric along its anterior–posterior (A–P) and dorsal–ventral (D–V) axes. It has an anterior micropyle and anterior dorsal appendages, a posterior aeropyle, and the egg is more curved on the ventral than on the dorsal surface.

two types of stem cells in the ovary: GSCs and somatic follicle stem cells (SSCs, **Figure 3**; Margolis and Spradling, 1995; Spradling *et al*., 1997, 2001). The anterior of each developing germarium hosts on average 2 or 3 GSCs, each of which is located adjacent to two or three somatic cap cells (Forbes *et al*., 1996a; Spradling *et al*., 1997; Xie and Spradling, 2000). Anterior to the cap cells in each ovariole are about six terminal filament (TF) cells which are arranged in a single-file array resembling a stack of pancakes. To the posterior of the cap cells and surrounding the GSCs and newly formed cystocytes are

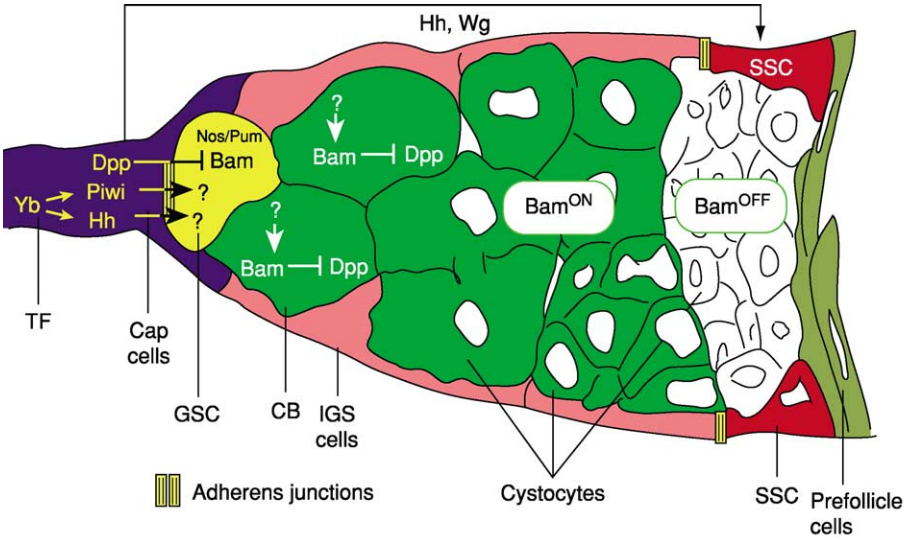

Figure 3 The ovarian germline and somatic stem cell niche. The germline stem cells (GSCs, yellow) and somatic stem cells (SSCs, red) are maintained in a somatic niche in germarial region 1, illustrated here. The stem cell niche is composed of terminal filament cells (TFs, blue), cap cells (blue), and inner germarial sheath cells (IGS, pink). TF and cap cells express Yb, Piwi, and the signaling molecules Dpp, Wg, and Hh, which act together to coordinate the two stem cell populations. GSCs maintain close contact with the cap cells through *adherens* junctions. Dpp signaling activity is restricted to GSCs where it maintains GSC fate by repressing Bam transcription, thereby preventing differentiation. When a GSC divides, one daughter maintains contact with the cap cells and remains a GSC, while the other daughter (the cystoblast – CB) escapes the niche and activates Bam expression (Bam^{ON}, shown in green). Bam is required to execute the cystoblast division program of four incomplete divisions, forming 16-cell cysts that no longer express Bam (Bam^{OFF}). In addition to intercellular signaling pathways, cell-autonomous factors like the translational repressors Nanos and Pumilio (Nos/Pum) are required in the germline for the maintenance of GSCs. SSCs are located at the boundary between germarial regions 1 and 2, and serve as the source of prefollicle cells (brown) that will encapsulate individual cysts. *Adherens* junctions between the SSCs and IGS cells retain SSCs in their niche. Hh and Wg are the only known signals for maintaining SSCs. Yb is expressed in the TF and cap cells where it activates the Piwi pathway for GSC maintenance, and the Hh pathway for both GSC and SSC maintenance. Molecular targets of Piwi, Hh, and Wg in stem cell maintenance have not been identified.

the inner germarial sheath (IGS) cells (**Figure 3**; Godt and Laski, 1995; Chen *et al*., 2001).

The TF cells, cap cells, and IGS cells constitute the stem cell niche – the cellular microenvironment that regulates, induces and supports the development of stem cells (**Figure 3**; review: Spradling *et al*., 2001). The TF and somatic cap cells are the likely sources of several important signaling molecules, and the survival of GSCs is dependent on their close association with these cells. Niche function also depends on the continued presence of stem cells, since empty niches eventually degenerate (Xie and Spradling, 2000). Thus, the GSCs and the stem cell niche function together to maintain the size of the stem cell pool, and allow the regular production of new egg chambers (Spradling *et al*., 2001; Lin, 2002; Gonzalez-Reyes, 2003; Kai and Spradling, 2003).

Cap cells and TF cells can be visualized with a *hedgehog-lacZ* enhancer trap and the IGS cells can be identified by *patched-lacZ* expression (Forbes *et al*., 1996a). The GSCs can be recognized because of their large size, location, and the presence of a cytoplasmic organelle called a spectrosome that is invariably anchored to the cap cell-GSC contact site (**Figure 1**; Lin *et al*., 1994; de Cuevas and Spradling, 1998).

1.2.2.2. Somatic Stem Cells

Continued generation of follicle cells is ensured by the maintenance of two or three somatic stem cells that are found at the surface of the germarium at the 2A/2B boundary (**Figures 2 and 3**). The immediate progeny of the SSCs, the follicle cell progenitors, divide to generate different classes of follicle cells that encapsulate each germline cyst. No positive marker for the SSCs has been described so far and they cannot be recognized by morphology or position, thus complicating their study. The SSCs have been identified as the only mitotically active somatic cells that remain in the germarium and continue to divide after being genetically marked (Margolis and Spradling, 1995). Zhang and Kalderon (2001) noted that the anterior-most mitotically active somatic cells fail to stain with Fasciclin III (FasIII) antibodies, which mark differentiating follicle cells, and have suggested that these are the SSCs.

1.2.2.3. Stem Cell Niche Cell Adhesion

During late larval and early pupal development, the somatic mesoderm starts to differentiate, dividing the ovary into individual ovarioles. The TFs form during the second half of the third larval instar. *Adherens* junctions form between the cap cells and the newly established GSCs during early pupation (**Figure 3**). After the formation of the TFs and the cap cells, the anterior primordial germ cells (PGCs) are selected to become GSCs while the rest of the PGCs are thought to enter directly the cyst differentiation pathway (Bhat and Schedl, 1997; Song *et al*., 2002; Zhu and Xie, 2003).

Cell adhesion mediated by DE-Cadherin plays an important role during late larval development in the recruitment of PGCs to the stem cell niche where they become GSCs (Song and Xie, 2002). Without DE-Cadherin, germline cells are not efficiently incorporated into the niche as stem cells. Contact between germline cells and newly differentiated cap cells seems to initiate the establishment of stable *adherens* junctions between them. The *adherens* junction components, DE-Cadherin and Armadillo (Arm; β-Catenin), are concentrated at the interfaces between the cap cells and GSCs. These *adherens* junctions are essential to hold the GSC in the niche and, therefore, maintain its stem cell identity (**Figure 3**; Lin and Spradling, 1993; Xie and Spradling, 1998). Removal of DE-Cadherin or Arm from the GSCs allows them to leave the stem cell niche and differentiate (Song and Xie, 2002).

The GSCs divide to produce cystoblasts that differentiate into germline cysts (**Figure 1**). GSCs divide along the A–P axis of the germarium so that the anterior daughter remains anchored to the cap cells and retains stem cell identity. The other daughter, now one cell diameter from the cap cells, differentiates as a cystoblast and begins oogenesis (Lin and Spradling, 1997). Stem cells and cystoblasts are connected by a transient ring canal (Carpenter, 1981; de Cuevas and Spradling, 1998). Before either cell divides again, the ring canal shrinks and the connection between the two cells is severed. The GSCs are randomly lost to differentiation, with a half-life of about 4–5 weeks (Margolis and Spradling, 1995; Xie and Spradling, 1998). When a GSC is lost, the remaining stem cells can divide perpendicular to the A–P axis so that both daughters remain attached to the cap cells (Xie and Spradling, 2000; Zhu and Xie, 2003). This division pattern suggests that symmetrical GSC division replenishes any vacant niche spaces.

As with GSCs, Cadherin-mediated cell adhesion is probably required for anchoring SSCs to their stem cell niche (Song and Xie, 2002, 2003). The SSCs interact directly with the IGS cells, which may function as the SSC niche. DE-Cadherin and Arm accumulate at the border between SSCs and IGS cells, and removal of DE-Cadherin or Arm from the SSCs allows them to move away from their niche and differentiate. While the asymmetry of GSCs divisions is clearly marked by asymmetric cytoplasmic inheritance of the spectrosome (Section 1.2.3.3), the division of a SSC is not necessarily asymmetric: the different behavior of the SSC daughters can be explained if the stem cell niche has a limited capacity and one daughter cell must leave the niche after division.

1.2.2.4. Stem Cell Niche Communication

Signals emanating from the GSC niche are required for the maintenance of both the GSCs and the SSCs. TF and cap cells express the genes *Yb*, *piwi*, *decapentaplegic* (*dpp*), *wingless* (*wg*), and *hedgehog* (*hh*), which are part of an intercellular signaling network that coordinates the two stem cell populations (**Figure 3**). Intrinsic factors, including the Decapentaplegic (Dpp) receptor, Pumilio (Pum) and Nanos (Nos), are required in the GSCs for maintenance.[1]

1.2.2.4.1. Dpp Dpp, the *Drosphila* homolog of TGF-β/BMP, is secreted by the somatic cells in the stem cell niche and received by the GSCs, where the Dpp signaling pathway is activated (Xie and Spradling, 1998, 2000; Song *et al*., 2004). The *dpp* mRNA is expressed in the cap cells, and the Dpp receptor, and downstream proteins in the signaling pathway, are required in the GSCs. Overexpressing *dpp* in somatic cells is sufficient to induce more GSCs, and misexpression of *dpp* or ectopic activation of the Dpp pathway in GSCs results in germ cell overproliferation, indicating that Dpp signaling stimulates GSC division and represses differentiation of the daughter cells. GSCs lacking Dpp receptors are replaced by wild-type germline cells, which come to lie next to the cap cells and behave as GSCs, indicating that the Dpp signal maintains GSCs in a niche that is able to program newly introduced cells to become stem cells. In fact, Dpp appears to be sufficient to cause four- and eight-cell germline cystocystes to de-differentiate and repopulate the GSC niche (Kai and Spradling, 2004).

The activity of *dpp* maintains GSCs in their niche because it represses the expression of *bag of marbles* (*bam*) (Chen and McKearin, 2003b; Song *et al*., 2004), a factor required to resume a program of

[1]An appendix at the end of this chapter includes a list of gene names, their abbreviations, and a short description of their functions.

cyst cell division and differentiation (McKearin and Spradling, 1990; McKearin and Ohlstein, 1995). The *bam* gene is expressed in the cystoblasts but not in the GSCs (**Figure 3**; McKearin and Ohlstein, 1995; Chen and McKearin, 2003b). Overexpression of *bam* in GSCs effectively eliminates the GSC fate, similar to the loss of *dpp* signal transduction in the GSCs (Ohlstein and McKearin, 1997). Significantly, loss of *dpp* expression in the stem cell niche quickly allows the expression of *bam* in the GSCs (Song *et al*., 2004). Conversely, broad expression of *dpp*, directly prevents *bam* transcription and blocks the differentiation of GSC daughter cells (Chen and McKearin, 2003a). *bam* appears to be the principal Dpp target because ectopic Bam expression is sufficient to restore differentiation to Dpp-overexpressing cells, and because the *bam* promoter contains a transcriptional silencer element that binds the Mothers against Dpp (Mad) and Medea proteins (Chen and McKearin, 2003a, 2003b; Song *et al*., 2004). The simplest explanation for these results is that Dpp functions as a short-range signal that promotes GSC survival by repressing *bam* expression specifically in the GSCs and preventing their differentiation as cystoblasts.

1.2.2.4.2. Nanos and Pumilio The RNA binding proteins Nanos (Nos) and Pumilio (Pum) are required in the germline for the maintenance of GSCs (Lin and Spradling, 1997; Forbes and Lehmann, 1998; Bhat, 1999; Parisi and Lin, 1999). Ovaries mutant for *nos* or *pum* have very few germ cells, and the number of germ cells decreases with age, suggesting that these two genes are required for GSC maintenance (Forbes and Lehmann, 1998; Bhat, 1999; Wang and Lin, 2004). *nos* is expressed at a high level in all PGCs in the third instar larval ovary. If *nos* function is removed during this period, a large proportion of PGCs, including those in contact with the stem cell niche, prematurely differentiate into cysts (Wang and Lin, 2004). These results indicate that *nos* activity maintains GSC self-renewal by preventing differentiation. The ovarian phenotype of a *nos pum* double mutant is similar to either *nos* or *pum* alone (Wang and Lin, 2004), suggesting they act as partners in GSC maintenance. As a Nos/Pum complex acts as a translational repressor in later stages of oogenesis (review: Parisi and Lin, 2000), these molecules are presumed to maintain GSC fate by repressing translation of one or more mRNAs required for differentiation.

1.2.2.4.3. Hedgehog and Wingless Hedgehog (Hh) and Wingless (Wg), expressed by the TF and cap cells, are the only known signals required for the maintenance of somatic stem cells (SSCs) (Forbes *et al*., 1996a, 1996b; Zhang and Kalderon, 2000, 2001; King *et al*., 2001; Song and Xie, 2003). Loss of Wg signal transduction or constitutive activation of the Wg pathway in SSCs results in their rapid loss, suggesting that correct intermediate levels of Wg signaling are important for proper regulation of SSCs. In addition, constitutive Wg signaling causes overproliferation and increased differentiation of polar cells and stalk cells (Section 1.2.5.3), causing defects in egg chamber budding and abnormal egg chamber morphology. Hh also regulates directly SSC maintenance and proliferation. Unlike *wg*, however, overexpression of *hh* induces SSC proliferation; like *wg*, a reduction in Hh signaling causes rapid SSC loss and arrests egg chamber budding.

Hh may also have a partially redundant function in GSC maintenance, since loss of *hh* causes loss of about 20% of the GSCs, while its overexpression stimulates a slight increase in the number of GSCs. The hypothesis that Hh positively regulates GSC survival is further supported by the observation that *hh* overexpression restores GSC maintenance to both *piwi* and *Yb* mutants (see below).

1.2.2.4.4. Piwi and Yb Two other genes known to be involved in maintaining stem cell survival are *piwi* (Cox *et al*., 1998, 2000), and *Yb* (King and Lin, 1999; King *et al*., 2001). Overexpression of either gene allows the specification of extra GSCs, while loss of either leads to the differentiation of GSCs into a few dividing cystoblasts, thus depleting the germline. Both are expressed and autonomously required in the TF cells and cap cells. *piwi* is also expressed in the germline, but is required specifically in the somatic cells for GSC maintenance. In *Yb* mutant germaria, *piwi* expression is specifically eliminated in the TF and cap cells, suggesting that *Yb* acts through *piwi* to maintain GSCs.

Piwi is likely to be of fundamental importance as it is the founding member of a conserved class of proteins (the Piwi, Argonaute, or PPD family) that function in stem cell maintenance in both the animal and plant kingdoms (reviews: Benfey, 1999; Cerutti *et al*., 2000). The step of gene expression on which Piwi may exert regulation is unclear, as Piwi-related proteins have been implicated in several DNA- and RNA-related processes including RNA interference (Smulders-Srinivasan and Lin, 2003).

Yb is a positive regulator of both *hh* and *piwi* expression. Since *hh* is required primarily for SSC maintenance, and *piwi* is required primarily for GSC maintenance, Yb appears to coordinately regulate SSCs, through *hh*, and GSCs, through *piwi*, *hh*, and an uncharacterized signal (King *et al*., 2001). Yb

regulates SSC proliferation by autonomously activating *hh* expression in the stem cell niche. Ectopic *hh* expression can induce SSC proliferation and partially restore GSC maintenance to *Yb* mutants, suggesting that *Yb* acts upstream of *hh* to regulate both stem cell populations.

While *piwi* and *hh* are both involved in maintaining GSCs, it is believed that they function in separate parallel pathways, with *piwi* having the more important role in normal development. However, *hh* overexpression increases the number of GSCs even in *piwi* mutants, therefore ectopic *hh* is able to rescue the GSC loss phenotype of *piwi*. It is unlikely that this effect comes about through an Hh-dependent increase in the capacity of the niche, as overexpression of *dpp* does not rescue the effects of *piwi* on GSC number (King *et al.*, 2001).

1.2.3. Germline Cyst Formation

The mitotically active region at the anterior of each ovariole is termed the germarium. It can be divided into four regions organized along the A–P axis (1, 2A, 2B, and 3) that correspond to maturing cyst stages (**Figures 2** and **3**). Region 1 contains 2–3 GSCs, cystoblasts and interconnected cysts of 2, 4, or 8 cells. Two or three GSCs occupy the apical position in each ovariole and are in close contact with several anterior somatic cells (**Figure 3**). GSC division produces a new GSC that remains in the position of the mother cell, and a second posterior daughter that develops as a cystoblast (King, 1970). The cystoblast divides four times with incomplete cytokinesis at each division, producing a syncytial cluster of 16 interconnected cystocytes (the cyst; **Figure 1**). Comparative analyses of germ cell development suggest that similar cell lineages arise during gametogenesis in diverse organisms (de Cuevas and Spradling, 1998; Pepling *et al.*, 1999). Cytokinesis is incomplete, since cleavage furrows are arrested and become stabilized as ring canals (see below). Similar ring canals form in most germ cells, including those from vertebrate models, and may serve to synchronize germ cell maturation (Pepling *et al.*, 1999).

Prefollicle cells, produced by 2–3 SSCs that reside on the side of the germarium at the regions 2A/2B (**Figure 3**), surround the germline cysts to form an epithelium and separate cysts from one another (**Figures 2** and **3**). The newly formed follicles or egg chambers change from spherical to elliptical so that they span the entire width of the germarium. The oocyte is centrally located in the cyst at this time. In regions 2B and 3, the newly specified oocyte takes up a posterior position as the cyst again changes shape to become spherical as it buds from the germarium as a stage 1 egg chamber (**Figure 2**). Under controlled conditions, it takes 3 days for a cystoblast to develop into a 16-cell cyst (King, 1970), and 7 days to reach stage 1 egg chamber (Wieschaus and Szabad, 1979). Then development of an egg progresses rapidly and is complete within 3 additional days (Lin and Spradling, 1993).

1.2.3.1. Ring Canals

During oogenesis of many insects, including *Drosophila*, cytoplasmic bridges called ring canals allow the flow of materials among the nurse cells and the oocyte. Ring canals can be visualized by staining with fluorescently labeled phalloidin, which binds to filamentous Actin, or with antibodies directed against ring canal components. The division pattern of the germline cyst leads to only two cells with four ring canals (**Figure 1**). The ring canal connecting the two daughter cells of the first division is the largest in diameter, and those arising at the second, third, and fourth divisions are each smaller than the previous ones. Ring canals have an electron-opaque outer ring associated with membranes and an electron-dense inner rim of Actin, the Hu-Li Tai Shao ring canal (Hts-RC) protein, and Kelch. Their assembly involves the sequential addition of proteins that transform the arrested cleavage furrow into a stable intercellular bridge (de Cuevas and Spradling, 1998). Although the inner rim is established coordinately with the degeneration of the fusome (see below) and the addition of Actin to the ring canal, the fusome is not required for arrest of the contractile ring or to initiate ring canal formation (Section 1.2.3.2; Lin *et al.*, 1994).

An outer-rim component that is recognized by anti-phosphotyrosine antibodies begins to mark ring canals in the early germarium, as the cleavage furrows arrest in the final round of cyst mitosis (Robinson *et al.*, 1994). Next, the electron-dense inner ring is formed as Cheerio (Filamin), then Actin and Hts-RC, are added starting in region 2A (Yue and Spradling, 1992; Theurkauf *et al.*, 1993; Robinson *et al.*, 1994). Female sterile *cheerio* mutants fail to recruit Hts-RC and Actin to the ring canals (Yue and Spradling, 1992; Robinson *et al.*, 1997). Kelch is the last known component to be added to the ring canals and it is added only after the Actin filament structure of the ring canals is complete (Tilney *et al.*, 1996). After Kelch is added, it is required through oogenesis for the continued expansion of the ring canals. *kelch* mutants initially form normal ring canals, which then become disorganized, resulting in female sterility due to transport blockage from the nurse cells into

the oocyte (Section 1.2.6.4; Xue and Cooley, 1993; Robinson and Cooley, 1997).

1.2.3.2. The Fusome

Reconstruction of the GSC, cystoblast, and cystocyte divisions by electron microscopy (EM) and confocal microscopy demonstrated that mitotic spindles are coordinately oriented during these divisions (King, 1970; Lin and Spradling, 1995). This is accomplished by anchoring one spindle pole of each dividing cell to a complex organelle termed the fusome (**Figure 1**; McGrail and Hays, 1997). Fusomes can be found in many insect germ cells (Büning, 1994), and similar organelles may exist in mammalian lymphocytes (Gregorio *et al*., 1992; McKearin, 1997), and germ cells (Pepling and Spradling, 1998). The organelles are spherical in GSCs and cystoblasts but grow to become elongated, branched structures that extend through each ring canal as cysts form (**Figure 1**).

Mutations in genes encoding fusome proteins, such as *hts* or *α-spectrin*, block fusome formation and cause premature termination of cyst divisions (Lin *et al*., 1994; de Cuevas *et al*., 1996). Thus, fusome integrity is essential for proper execution of cyst divisions. In the absence of fusomes, cystocyte spindles are disoriented, mitoses are not synchronized, and cystocytes usually do not complete four full divisions, emerging with unusual number of cystocytes such as 3, 5, or 6. Cysts are approximately of normal size because each cystocyte assumes a volume greater than the average wild-type cystocyte volume. Although cysts containing fewer than 15 nurse cells can complete oogenesis (Mata *et al*., 2000; D. McKearin, unpublished data), females carrying fusome-inactivating mutations are almost always sterile because cysts fail to form an oocyte. This observation reveals a second role for fusomes in cyst formation – oocyte determination depends on the fusome, probably because it establishes polarity within the cyst (Section 1.2.4.1).

Genetic and immunolocalization studies in *Drosophila* have identified a large group of proteins found associated with fusomes (**Table 1**). Our current view of the organelle is that membrane skeleton proteins form a meshwork within which membranous cisternae are embedded. Ultrastructural features suggest that fusome cisternae represent a germ cell-specific modification of the endoplasmic reticulum (ER) (Büning, 1994). The finding that an ER-associated protein, Ter94, is a fusome component was consistent with this hypothesis. Furthermore, green fluorescence protein (GFP) that carries ER-targeting signals localizes to the fusome (N. Liu and D. McKearin, unpublished), adding additional support to the idea that the fusome is the site of ER assembly in germ cells.

1.2.3.3. The Fusome Cycle

As indicated above, an asymmetric GSC division produces another GSC and a cystoblast, while asymmetric cystocyte divisions produce 15 nurse cells and a single oocyte. The intrinsic factors that underlie the asymmetric fates of GSC and cystocyte divisions are largely unknown but some features of the asymmetry are clear. Unequal fusome distribution is one prominent manifestation of intrinsic asymmetry, since the future cystoblast inherits a smaller fraction of fusome material than the GSC (**Figure 1**) (Deng and Lin, 1997; de Cuevas and Spradling, 1998). During cyst divisions, the oldest cystocyte always retains the largest fraction of

Table 1 Fusome proteins

Protein	*Function*	*Mutant phenotype*	*Reference*
α-Spectrin	Membrane skeleton	No fusome	de Cuevas *et al.* (1997)
β-Spectrin	Membrane skeleton	No fusome	Lin *et al.* (1994)
Ankyrin	Scaffold or linker protein	n.d.	de Cuevas *et al.* (1997)
Actin	Cytoskeleton structure, diverse	n.d.	Hime *et al.* (1996), Kai and Spradling (2003)
Bag of marbles	Novel	Reticulum disrupted	McKearin and Ohlstein (1995)
Cyclin A	CDK component	Cell lethal	Eberhart *et al.* (1996)
Dynein	Motor	Disoriented mitoses	McGrail and Hays (1997)
Encore	Cullin-binding protein	>16 cystocytes	Ohlmeyer and Schüpbach (2003)
Hu-Li Tai Shao	Adducin related, cytoskeleton	No fusome	Lin *et al.* (1994)
KLP61	Kinesin-like motor	Disoriented mitoses	Wilson (1999)
Lis-1	Lissencephaly ortholog	<16 cystocytes	Liu *et al.* (1999)
Orbit	Microtubule binding protein, CLASP ortholog	Poor cyst formation, GSC loss	Mathe *et al.* (2003)
Par-1	Microtubule binding protein	No oocyte	Cox *et al.* (2001a), Huynh *et al.* (2001b)
Spectraplakin	Cytoskeletal linker protein	No oocyte	Roper and Brown (2004)
Ter94	ER assembly, vesicle fusion	Cell lethal	Leon and McKearin (1999)

fusome material, perhaps anticipating which cell will become the oocyte (de Cuevas and Spradling, 1998; see below). The recognition of Bag of marbles (Bam), as both a fusome-associated protein (McKearin and Ohlstein, 1995) and a regulator of cystoblast differentiation, underscores a role for the fusome in germline asymmetric divisions (McKearin, 1997).

de Cuevas and Spradling described the fusome cycle in considerable detail and proposed that the remarkable dynamics of fusome morphogenesis could account for oocyte specification (de Cuevas and Spradling, 1998). Starting with the cystoblast as an example, the centriole at one spindle pole is anchored to the fusome, and the spindle body extends away from this point. Cytokinesis arrests as the contractile ring approaches the spindle midbody, and fusome proteins appear to aggregate in the gap separating the two daughters. This ring canal-associated piece of fusome is connected to the parent fusome by microtubules, and gradually the distance between the fusome pieces closes until they fuse. This process is almost certainly mediated by microtubules (MTs) and MT-associated motor proteins, since mutations affecting several MT-binding proteins disrupt fusome assembly and leave fusomes fragmented (e.g., *dynein* or *orbit* mutations). The cycle of gathering ring canal-associated fusome aggregates into a single coherent organelle is repeated at each cystocyte division until the fusome is large and branched.

The GSC fusome is unique in several ways. In electron micrographs, it contains only a sparse collection of small, spherical vesicles compared to cyst fusomes. The GSC fusome also occupies a stereotypical position in stem cells – at the anterior-most pole where the GSC is anchored to the cap cells via *adherens* junctions (Xie and Spradling, 2000). The unique features of the GSC fusome are recognized by giving it a special name, the spectrosome. Viewed with Hts antibodies, the spectrosome is a large dot during interphase but elongates to stretch across the entire A–P axis of the GSC near the end of mitosis. The GSC and cystoblast remain connected for some time through an intercellular bridge that is unstable and eventually closes to separate the cells. One end of the stretched spectrosome remains anchored at the anterior end of the GSC while the other end traverses the intercellular bridge and enters the presumptive cystoblast's cytoplasm. When the transient-bridge closes, it splits the resulting single fusome into unequal portions with the stem cell retaining a greater portion (Deng and Lin, 1997). The spectrosome in the GSC returns to the anterior of the cell and regains its spherical shape.

It is always one of the two cystocytes arising from the first cystoblast division that is determined to become the oocyte, while the remaining cells become nurse cells. Throughout cyst divisions, one of the two cells from the first division retains more fusomal material than any other cell (Lin and Spradling, 1995; de Cuevas and Spradling, 1998; Deng and Lin, 2001). Persistent asymmetry in the fusome indicates the presence of early cues capable of distinguishing the two pro-oocytes by cytoplasmic inheritance (de Cuevas and Spradling, 1998). In *Drosophila*, oocyte markers accumulate after the fusome starts to break down, so a direct lineage cannot be established between the cell retaining the most fusomal material and the oocyte. In *Dytiscus*, however, a visible ring of highly amplified ribosomal DNA is inherited by the future oocyte at the first cyst division, and this cell also inherits the fusome (de Cuevas and Spradling, 1998, and references therein). These results support the model that the initial asymmetry of the first cyst division is maintained through subsequent divisions and plays an central role in specifying oocyte fate (Section 1.2.4.1; Lin *et al*., 1994; Theurkauf, 1994a).

1.2.3.4. Counting Cystocyte Cell Divisions

The strict reproducibility of the number of cystocyte divisions is a remarkable feature of germline cysts. In *Drosophila melanogaster*, the cystoblast divides precisely four times with incomplete cytokinesis to produce a syncytium of 16 cells. Wild-type cysts rarely vary from this pattern of divisions. Despite the regularity of the number of cystocyte divisions, the counting mechanism can be manipulated or overridden by misexpression or inactivation of several cell cycle regulators. Lilly *et al*. (2000) showed that the induction of high levels of a degradation-resistant form of Cyclin A (CycA) causes a significant fraction of cysts to form with 32 cells. The same is true for misexpression of stabilized Cyclin B (CycB), albeit at a lower frequency. While misexpression of the G1 Cyclin E (CycE) does not produce 32-cell cysts, females heterozygous for an inactivating *cycE* allele produce cysts with only eight cells. Perhaps the simplest explanation for these observations is that the cystocyte counting mechanism is sensitive to the absolute length of each cell cycle and that the mitotic rate is controlled, in part, by the absolute concentration of the G1 and G2 cyclins. This suggests that cystocytes must complete their divisions within a specific time or region of the germarium as they move posteriorly.

While the biochemistry of counting the cystocyte divisions is unknown, the process is clearly controlled

genetically, since several mutations that disrupt the counting mechanism have been identified. Several of these genes have been implicated in the control of cyclin stability and it is likely that they exert their effects by premature destabilization or inappropriate stabilization of one or more cyclins. For example, inactivating alleles of the *UbcD1* E2 ubiquitin-conjugating enzyme cause extra cystocyte divisions and thus phenocopy the effect of CycA overexpression (Lilly *et al*., 2000). The extra rounds of cystocyte mitoses can be suppressed by removing one copy of the *cycA* gene, suggesting that the *UbcD1* effect is mediated by inappropriate perdurance of mitotic cyclins.

Using a screening strategy that permits gene misexpression, Mata *et al*. (2000) determined that cystocyte counting mechanisms can be altered by overexpressing the *Drosophila* Cyclin-dependent kinase Cdc25 homologs, *string* (*stg*) and *twine* (*twe*). The activity of Cdc25-like proteins is a rate-limiting step in *Drosophila* cell cycles as the *string* and *twine* phosphatases derepress the Cyclin-dependent kinase Cdk1 to initiate the G2/M transition. Surprisingly, overexpression of *string* causes cysts to form with only eight cystocytes, in contrast to the extra cystocyte divisions caused by CycA overexpression. The fact that ectopic Cdk1 activity causes fewer cystocyte divisions, while stable expression of one of its obligate partners, CycA, causes supernumerary divisions, indicates that critical features of the mitotic counting mechanism remain mysterious.

The misexpression screen for mitotic dysregulation also revealed two genes that caused extra cystocyte divisions, *tribbles* (*trbl*) and *grapes* (*grp*) (Mata *et al*., 2000). Grapes (Grp) was identified previously as an inhibitory kinase of Cdc25-like proteins (Ohi and Gould, 1999), and, therefore, its overexpression phenotype in cysts can be interpreted as a super-repression of String activity. The effects of Tribbles misexpression are particularly striking as ~90% of the cysts contained 32 cells. Elegant biochemical and genetic experiments showed that Tribbles inhibits String and Twine in embryonic and cystocyte cell cycles by causing protein degradation (Mata *et al*., 2000). Thus, mitotic entry is delayed in cystocytes expressing too much Tribbles.

Inactivating mutations in the *encore* (*enc*) gene also produce 32-cell cysts with high frequency (Hawkins *et al*., 1996). While Encore (Enc) is novel, a recent study clarified the *encore* loss-of-function effect by showing that the protein is necessary for proper assembly of the SCF-complex (Skp/Cullin/Rbx1/F-box) on the fusome (Ohlmeyer and Schüpbach, 2003). In germ cells lacking *encore*, failure of the fusome-associated SCF-complex to degrade CycE in a timely fashion leads to CycA overactivity, which can cause extra cystocyte divisions (see above). Regulation of the counting mechanism by *encore* demonstrates that the fusome plays a critical role in cystocyte divisions. Mutations in core fusome components, such as *hts* or *α-spectrin*, cause cysts with fewer than 16 cystocytes to form (Yue and Spradling, 1992; de Cuevas *et al*., 1996). The effect of mutations affecting fusome structure is somewhat different from those in *cycE* and *tribbles* since cystocyte divisions are largely asynchronous in *hts* and *α-spectrin* mutants. Mitotic spindle misorientation probably accounts for the more profound effect of mutations that block fusome formation (Lin *et al*., 1994; de Cuevas *et al*., 1996).

It is not surprising that dysregulation of cell cycle regulators would affect cystocyte counting mechanisms, but the expression patterns of these proteins do not correlate with the timing of the four cystocyte divisions. On the other hand, Bam protein begins to accumulate in the cystoblast, its abundance increases throughout the first three cystocyte cycles, and then it disappears at or shortly after the fourth division (**Figure 3**). Thus, Bam has exactly the profile expected of a protein that acts as a meter of the four-division cycle. The female germline *Bam* mutant phenotype did not reveal a role as a cystocyte division factor since the gene is necessary for cystoblast differentiation. Mutations in *Bam*, however, are able to suppress the supernumerary divisions observed in ovaries lacking *encore* (Hawkins *et al*., 1996) or overexpressing stable CycA (Lilly *et al*., 2000). Finally, discontinuous *Bam* expression from heat-inducible transgenes can rescue cystoblast and cyst formation but often leads to cysts with fewer than 16 cells, suggesting that *Bam* is required throughout the cyst division cycles to complete four mitoses (Ohlstein and McKearin, 1997; D. McKearin, unpublished data).

As Bam is a novel and rare protein, the biochemical mechanism by which it regulates cyst formation remains unclear. Bam is cytoplasmic (McKearin and Ohlstein, 1995) and works together with Benign gonial cell neoplasm (Bgcn), an unusual RNA helicase-like protein, suggesting that the Bam : Bgcn complex may act by regulating translation of cystoblast promoting mRNAs (Ohlstein *et al*., 2000). Genetic and immunolocalization studies suggest that the mitotic cyclins and their regulators drive cystocyte divisions only as long as Bam is present. Perhaps Bam is degraded in newly formed 16-cell cysts in response to a signal received from somatic cells at the posterior of region 1. Once Bam is degraded, cystocyte divisions cease, and

cystocytes destined to be nurse cells switch to endoreduplicative cycles while the oocyte enters meiosis 1.

1.2.4. Early Oocyte Differentiation and Polarity

Once the oocyte fate has been specified, the oocyte condenses its DNA into a compact karyosome, arrested in prophase I until late in oogenesis. At the same time, the nurse cells endoreplicate their DNA, eventually reaching 2048C in those cells closest to the oocyte. While transcription from the oocyte nucleus remains relatively quiescent, the nurse cells transcribe and translate very actively, and steadily transfer mRNAs and proteins into the oocyte on a polarized microtubule (MT) cytoskeleton. The determination and maintenance of the oocyte fate depends on: (1) the launching of meiosis and its restriction to the oocyte; (2) the acquisition and maintenance of a single microtubule organizing center (MTOC) in the oocyte, for the collection of the mRNAs and proteins that are necessary to continue oogenesis; and (3) karyosome formation.

1.2.4.1. Establishing the Oocyte and Early Polarity

The oocyte-localized proteins Oo18 RNA binding protein (Orb), Bicaudal-D (Bic-D), Egalitarian (Egl), and Par-1 are required for oocyte differentiation; recessive mutations at these loci cause female sterility because egg chambers form 16 nurse cells and no oocyte (Schüpbach and Wieschaus, 1991; Vaccari and Ephrussi, 2002). All four proteins become highly enriched in several cells as early as the middle of germarial region 2A, as they move along the MT network and localize to the oocyte by region 2B (Lantz *et al.*, 1992; Lantz and Schedl, 1994; Mach and Lehmann, 1997; Pare and Suter, 2000). By this time, the nurse cell centrosomes have also migrated on the fusome to a single focus in the oocyte (a detailed description of centrosome migration can be found in Grieder *et al.*, 2000 and Section 1.2.4.1.1). Between region 2B and 3 of the germarium, the centrosome cluster, together with Orb, Egl, Bic-D, and Par-1, migrates from an anterior position to one between the oocyte nucleus and the posterior terminal follicle cells. Until the cytoskeleton is reorganized during stage 7, a single MT cytoskeleton emanates from this posterior MTOC through the ring canals into each nurse cell (**Figure 2**; Theurkauf *et al.*, 1993). mRNAs and proteins are steadily transported toward the MT minus-ends, so that they accumulate in the oocyte. This is a critical polarization event, and is the first indication of polarity within the oocyte itself. Without this posterior relocalization, the oocyte exits meiotic arrest and reverts to a nurse cell fate.

1.2.4.1.1. Centrosome migration A large MT network extends through all the cells of the early cyst before the centrosomes and MTOC are restricted to the oocyte (Grieder *et al.*, 2000). The fusome is embedded in this MT network throughout region 2A and 2B of the germarium. The MT minus ends, marked by a No distributive disjunctions (Nod) : β-Gal fusion protein, are enriched along the fusome, and by region 2B become concentrated in the central cells, then in the oocyte (**Figure 2**). In the absence of a fusome, in *hts* mutant cysts, the clustering of MTs to the fusome and oocyte was not observed at any time, so the fusome is necessary to organize MTs and focus them into the oocyte (Grieder *et al.*, 2000).

Centrosome migration into the oocyte does not depend on Bic-D, Orb, Egl, or Par-1 (Huynh and St. Johnston, 2000; Bolivar *et al.*, 2001; Vaccari and Ephrussi, 2002). It is Dynein-dependent, suggesting directed transport on a MT network, but it is also resistant to MT depolymerizing drugs such as colcemid, suggesting that centrosome migration is either MT-independent, or that it depends on a pool of stable MTs that are resistant to these drugs. The discovery of a new fusome component encoded by *short stop* (*shot*) supports the latter alternative (Roper and Brown, 2004). *shot* encodes a large cytoskeletal linker protein called spectraplakin that binds MTs, perhaps protecting them from depolymerizing drugs. Shot localizes to the fusome and is essential for organizing the cyst MT cytoskeleton, but is not required for fusome structure or stability, nor for the control of the number of cyst divisions. Loss of *shot* results in a 16-nurse cell phenotype in which Bic-D, Orb, and Dynein do not accumulate in a single cell. Therefore, *shot* acts downstream of the structural components of the fusome to specify oocyte fate. Interestingly, the cystocyte centrosomes do not migrate into the oocyte of *shot* mutants, but instead remain spread throughout the cyst. Acetylated α-tubulin, a marker for stable microtubules, clearly localizes to the fusome and colocalizes with Shot (Roper and Brown, 2004). In *shot* mutants, the level of acetylated MTs is reduced, and the association of these MTs with the fusome is lost. These results indicate that Shot mediates the association of stable MTs with the fusome. Without Shot, MTs fail to assemble on the fusome, the centrosomes do not localize to one cell, and the oocyte fails to become specified. The disruption of centrosome migration in shot mutants

can be explained by the migration of centrosomes on a MT network that is stabilized by Shot on the fusome (Grieder *et al*., 2000; Roper and Brown, 2004).

1.2.4.1.2. Restricting meiosis to the oocyte As the oocyte is the only cell that contributes genetic information to the egg, meiosis must be established within it, and repressed in the other germline cells that will become nurse cells. An initial stage of meiosis is synaptonemal complex (SC) formation. Meiosis, the mechanisms of SC formation, and meiotic recombination in *Drosophila* have been recently reviewed in detail (McKim *et al*., 2002). The behavior of SCs in the cyst suggests that oocyte fate is restricted gradually to one cell. The SC appears in two cells in the early region 2A, then spreads to the two cells with three ring canals, before it is restricted to two cells, and then finally to the oocyte in region 2B (Huynh and St. Johnston, 2000). The region 3 oocyte remains arrested at diplotene of meiotic prophase I (Carpenter, 1994), while the other 15 cells lose SCs and differentiate into nurse cells – via a series of endoreplication cycles. In later development, the oocyte completes prophase I, but undergoes a second meiotic arrest at metaphase I, which is released upon egg activation. In metazoans, meiosis is arrested at metaphase II, largely through the activity of the Mos kinase, and this arrest is released upon fertilization. Perhaps surprisingly, a recent analysis of a *mos* mutant in *Drosophila* does not support an essential role for this kinase in maintaining metaphase arrest (Ivanovska *et al*., 2004).

The first sign of oocyte identity, even before the SC has been restricted to the oocyte, is the specific accumulation of Bic-D, Egl, and Orb to one cell (Suter *et al*., 1989; Huynh and St. Johnston, 2000; Oh and Steward, 2001). Bic-D, Egl, and Orb seem to be involved in MT-dependent, Dynein-mediated transport of mRNA and protein from the nurse cells into the oocyte (Suter *et al*., 1989; Wharton and Struhl, 1989; Ran *et al*., 1994; Mach and Lehmann, 1997; Bullock and Ish-Horowicz, 2001; Chang *et al*., 2001). Orb is the *Drosophila* ortholog of cytoplasmic polyadenylation element binding (CPEB) protein, and is believed to stimulate translation of specific mRNAs that contain a cytoplasmic polyadenylation element (CPE) sequence by mediating an extension of their poly-A tails (Castagnetti and Ephrussi, 2003). Bic-D and Egl appear to function as core components of a Dynein motor complex that mediates minus-end directed transport (Mach and Lehmann, 1997; Karki and Holzbaur, 1999; Bullock and Ish-Horowicz, 2001; Matanis *et al*., 2002). In cultured human cells, the Bic-D ortholog also binds Dynein, and is capable of inducing rapid minus-end directed transport of experimentally tethered organelles such as mitochondria (Hoogenraad *et al*., 2003).

The *Bic-D*, *egl*, and *orb* mutant phenotypes indicate that these three proteins play an important role in restricting and maintaining SC formation to one cell. Loss of any one of these genes results in the formation of cysts with 16 nurse cells and no oocyte. In *egl* mutants, all 16 cells enter meiosis, reach full pachytene, and then revert to the nurse cell fate by region 2 of the germarium (Carpenter, 1994; Huynh and St. Johnston, 2000). Strong *orb* alleles also cause all cyst cells to form a complete SC, and most mutant cysts to degenerate in region 2. A hypomorphic *Bic-D* mutation shows a similar but weaker phenotype, where too many cells build synaptonemal complexes that disappear in region 3. In the complete absence of *Bic-D*, almost no SC formation can be detected using an SC antibody, though weak and diffuse staining is observed in all cells of some cysts (Huynh and St. Johnston, 2000). These results are most readily explained if Bic-D, Egl, and Orb are directly involved in restricting oocyte fate and SC formation to a single cell.

Individual mutations in *Bic-D*, *egl*, or *orb* also prevent the localization of the other two proteins to the oocyte (Suter and Steward, 1991; Lantz and Schedl, 1994; Machand and Lehmann, 1997). In *shot* mutants, they all fail to localize, the SC fails to refine to one cell, and is always lost by region 2B of the germarium (Roper and Brown, 2004). These data suggest that the effects of Bic-D, Egl, and Orb are mediated by their own localization to the oocyte. However, in the presence of drugs that depolymerize dynamic MTs, the SC becomes restricted to one cell of a wild-type cyst, even in the absence of localized Bic-D, Egl, or Orb accumulation (Huynh and St. Johnston, 2000), indicating that the function of these proteins in SC restriction does not depend on their own localization to the oocyte. Interestingly, SC restriction to the oocyte is not maintained in the presence of colcemid, therefore maintaining oocyte fate does depend on the MT-dependent localization of these determinants into the oocyte (see below).

Several other genes can mutate to give a 16-nurse cell phenotype, but their precise functions and relationships to *Bic-D*, *egl*, and *orb* are unclear. Hypomorphic alleles of *stonewall* (*stwl*) cause a 16-nurse cell phenotype, while in null alleles, cystoblasts and cysts are formed, oocyte differentiation fails, and all germ cells eventually undergo apoptosis. *stwl* encodes a DNA-binding protein with partial similarities to the mammalian Myb and Adf1 transcription

factors (Clark and McKearin, 1996), and domains that suggest its involvement in the regulation of chromatin remodelling. Targets for Stwl-mediated transcriptional regulation remain unidentified. The *shutdown* (*shu*) gene appears to function to maintain oocyte fate. In *shu* mutant ovaries, cysts usually have 16 cells, and one Bic-D positive cell begins to differentiate as an oocyte (Munn and Steward, 2000). However, these cells stop expressing oocyte markers during stages 1–3, and the cysts degenerate shortly thereafter. Mutations in a newly-identified gene, *soft boiled*, also result in a 16-nurse cell phenotype, but this gene has not yet been molecularly characterized (Morris *et al.*, 2003).

In addition to Bic-D, Egl, and Orb, many other RNAs and proteins accumulate in the early oocyte. Most of these have no known role in oocyte specification, but some are involved in later steps of axis patterning (Section 1.2.6). It appears, however, that mechanisms for localizing RNAs to the early oocyte are not especially selective, as one study indicates that almost 10% of randomly selected ovarian mRNAs become enriched in the early oocyte (Dubowy and Macdonald, 1998).

1.2.4.1.3. Maintaining oocyte fate The establishment of stable polarity within the oocyte, marked by the anterior-to-posterior relocalization of the oocyte centrosomes, together with Bic-D, Egl, Orb, and Par-1, is required to maintain MT-dependent transport of mRNAs and proteins into the oocyte and, therefore, maintain oocyte fate. Polarization of the oocyte requires the previous localization of at least Bic-D, Egl, Orb, and Par-1 (Bolivar *et al.*, 2001; Cox *et al.*, 2001a, 2001b; Huynh *et al.*, 2001a, 2001b). Par-1 posterior relocalization requires *Bic-D* and *orb* (and by association *egl*). In a *par-1* mutant, Bic-D, Orb, Egl, and the centrosomes still localize to one cell, and transiently localize together at the anterior of the oocyte. However, they do not relocalize to the posterior cortex, but instead remain associated with the remnants of the fusome, completely disrupting formation of a stable polarized MT network. Without posterior relocalization, Bic-D, Egl, and Orb localization in the cyst becomes diffuse, and the oocyte loses its fate, creating a cyst of 16 nurse cells. Therefore, establishing a stable posterior MTOC maintains meiotic arrest in the oocyte.

Essentially identical phenotypes have been observed for *par-1*, *bazooka* (*baz; par-3*), *par-5* (*14-3-3*), *par-6*, and *aPKC* (Cox *et al.*, 2001a, 2001b; Huynh *et al.*, 2001a, 2001b; Benton *et al.*, 2002; Vaccari and Ephrussi, 2002; Benton and Johnston, 2003). This family of genes, originally identified in *Caenorhabditis elegans* as cell polarity mutants, has an essential conserved role in establishing cell polarity (Ahringer, 2003; Etienne-Manneville and Hall, 2003). As in the *C. elegans* embryo, Par-1 and Baz are localized to complementary domains in the early *Drosophila* oocyte, and the anterior localization of Baz depends on posterior Par-1 localization (Vaccari and Ephrussi, 2002). Par-1 binds to the 14-3-3 proteins 14-3-3ε and 14-3-3ζ, and since the *14-3-3ε*; 14-3-3ζ double mutant phenotype is identical to the *par-1* phenotype, 14-3-3 proteins are thought to mediate Par-1 function (Benton *et al.*, 2002). Par-1 is a serine-threonine kinase and one of its targets is Baz. Par-1 can phosphorylate Baz, thus creating 14-3-3 binding sites. The PDZ domain proteins Baz and Par-6 normally form a tripartite complex with Atypical protein kinase C (aPKC) at the anterior of the oocyte (Benton *et al.*, 2002). Since 14-3-3 binding can inhibit interactions between aPKC and Baz, Par-1 can inhibit the assembly of Baz/Par-6/aPKC complexes (Benton and Johnston, 2003).

Taken together, this information suggests that Par-1 establishes cortical domains in the *Drosophila* oocyte by locally inhibiting Baz/Par-6/aPKC complex assembly, thus excluding Baz from the posterior of the oocyte. However, the mechanism by which these proteins affect MT polarity or dynamics is currently unknown. Furthermore, this model does not provide an explanation for how the oocyte is initially polarized. In *C. elegans*, Par-1 is recruited to the posterior cortex after the sperm centrosome defines the posterior pole. As such a cue is missing in *Drosophila*, it would be interesting to explore a possible relationship between establishing a posterior cortical Par-1 domain in the oocyte, and the cell adhesion surface established between the oocyte and the posterior follicle cells (Section 1.2.5.2).

1.2.4.2. The Spindle Genes, Meiotic Checkpoint, and Patterning

Mutations have been identified in several genes (*okra*, *spindle-A*, *-B*, *-C*, and *-D*, for example) that are required for repair of double-strand DNA breaks (DSBs) during meiosis (Ghabrial and Schüpbach, 1999; Staeva-Vieira *et al.*, 2003). In these mutants, the oocyte chromatin appears fragmented and thread-like, suggesting the presence of unrepaired DSBs. Thus, as in many other systems, recognition of DSBs activates a pathway that stops the progression of the cell cycle until the damaged DNA is repaired. This pathway is dependent on the *mei-41* function in *Drosophila*. Surprisingly, mutations in these genes also result in defects in axial patterning and in accumulation of the TGF-α

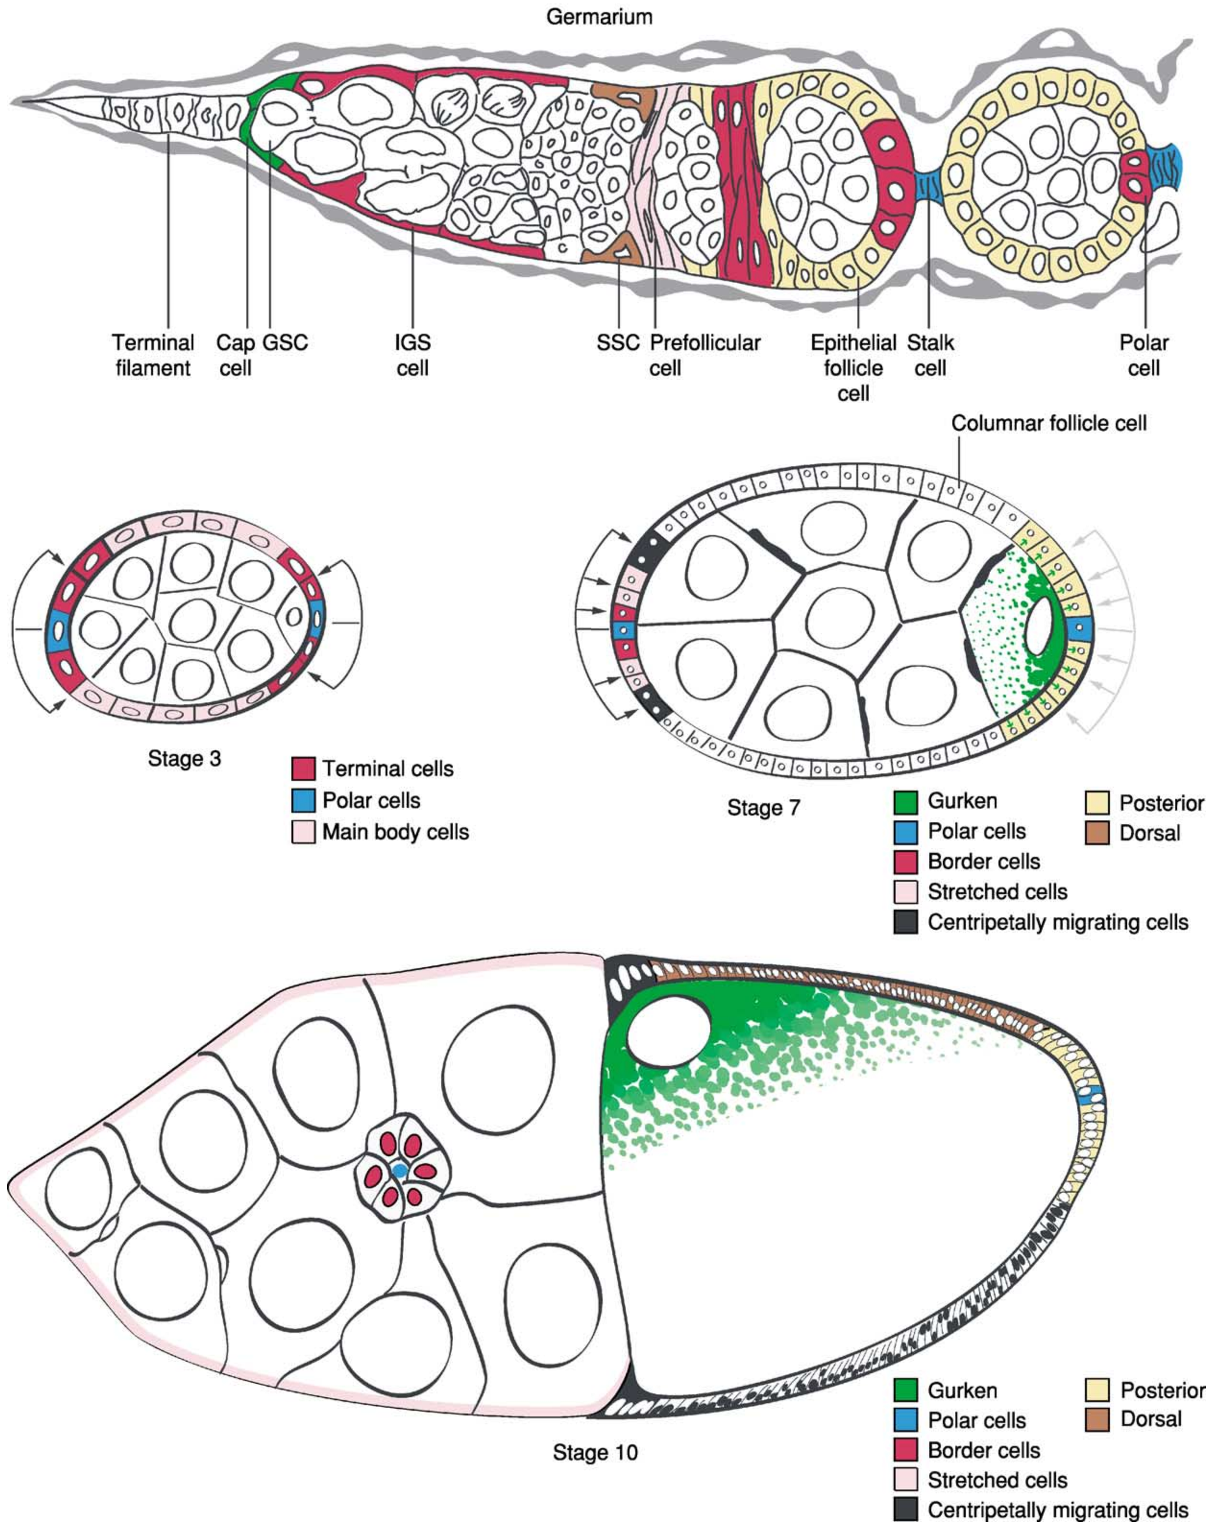

Figure 4 Cell types in the developing ovary. Top panel: There are two types of stem cells in the ovary: germline stem cells (GSCs) and somatic follicle stem cells (SSCs). The terminal filament cells, cap cells and inner germarial sheath (IGS) cells comprise the stem cell niche – the cellular microenvironment that regulates and supports the development of stem cells (discussed in Section 1.2.2). In germarial region 2B, the prefollicular cells invaginate from the germarium wall and encapsulate 16-cell cysts in order to complete the construction of individual egg chambers. These intercyst cells, the precursors of the polar cells and the intercyst stalk cells separate from the general follicle cell lineage and stop dividing by germarial region 3. Intercyst cells interdigitate to form a stalk during cyst separation from the germarium, and persist, anchored to the polar cells, so that adjacent egg chambers remain connected but not fused. Prefollicular cells divide and differentiate into a cuboidal monolayer of about 80 epithelial follicle cells that

ortholog Gurken (Grk) in the oocyte (Ghabrial and Schüpbach, 1999). This appears to occur because the *mei-41* dependent pathway downregulates Vasa (Vas) by posttranslationally modifying it. Vas, a probable translational activator (Section 1.2.7.1), is required for normal Grk accumulation (Styhler *et al.*, 1998), and presumably regulates the translation of one or more other mRNAs involved in DSB repair. *vas*-null mutant oocytes have fragmented chromosomes, similar to those in *okra* and *spindle* mutants that are not suppressible by *mei-41* (Ghabrial and Schüpbach, 1999). Phenotypes similar to those of the spindle mutations, including decreased Grk accumulation and aberrant posttranslational modification of Vas, have also been observed in a mutant Cop9 signalosome subunit 5 (*Csn5*) that affects a component of the Cop9 signalosome (Doronkin *et al.*, 2002). These results suggest that Csn5 might regulate the stability of one or more components of the DSB repair pathway.

There is controversy over whether Chk2, a kinase implicated in the response to DNA damage during mitotic replication (Takada *et al.*, 2003) and in the regulation of irradiation-induced p53-mediated apoptosis (Brodsky *et al.*, 2004), also has a role in meiotic DSB repair. Abdu *et al.* (2002) reported that a *chk2* mutation suppresses the effects of spindle-class mutations on Grk accumulation, and that Chk2 is phosphorylated and activated by the *mei-41* dependent pathway. They further report that Chk2 modifies two downstream proteins, Vas and Wee1, thus mediating the effects of DSBs on cell cycle progression, Grk accumulation, and oocyte nuclear morphology. In contrast, Masrouha *et al.* (2003) reported that *chk2* is not essential for normal meiosis and recombination, based on an analysis of X-linked nondisjunction, in which no *chk2*-dependent effects were observed. These workers did observe, however, accumulation of *chk2* RNA to the oocyte in early germarial stages, an expression pattern consistent with a meiotic function. Further work will be required to resolve this apparent paradox.

1.2.5. Follicle Cells

In germarial region 2B, the precursors of the follicle cells invaginate from the germarium wall and encapsulate 16-cell cysts in order to complete the construction of individual egg chambers (**Figure 4**; Margolis and Spradling, 1995). Groups of cells defining the anterior and posterior pole of each egg chamber separate from the general follicle cell lineage and stop dividing by germarial region 3 (Tworoger *et al.*, 1999). These intercyst cells are the precursors of the polar cells and the intercyst stalk cells (**Figure 4**). Intercyst cells interdigitate to form a stalk during cyst separation from the germarium, and persist, anchored to the polar cells, so that adjacent egg chambers remain connected, but not fused. The common precursors to stalk and polar cells are distinct from the precursors of the main body follicle cells and can be identified in the germarium using antibodies to the Big brain (Bib) protein (Larkin *et al.*, 1996). Bib is a positive regulator of Notch (N) signal reception and is expressed in the follicle cells that will intercalate to form the stalk, as well as fully developed stalk cells. The enhancer trap line P{lacW}B1-93F acts as a differentiated stalk cell marker (Ruohola *et al.*, 1991).

Prefollicular cells (**Figure 4**) divide and differentiate into a cuboidal monolayer of about 80 polarized follicle cells that surround the germline cyst to create the stage 1 egg chamber. As the nurse cells and oocyte increase in volume, the follicle cells divide to reach about 1000 cells per egg chamber by stage 6. Then, during stages 7–9, the follicle cells

surround the germline cyst to create the stage 1 egg chamber. Middle left panel: By stage 3 three distinct populations of follicle cells have become specified. Polar cells are adjacent to the anterior and posterior ends of the germline cyst, and the posterior polar cell is adjacent to the posterior pole of the oocyte. Terminal cells, specified by the Upd signal from the polar cells (arrows) flank the polar cells. Main body cells occupy lateral regions of the egg chamber. Middle right panel and bottom panel: During stages 7 and 8, the anterior follicle cells begin to migrate posteriorly toward the oocyte. The nature of their migration and their final destination has already been determined at this time, by a gradient of Jak activity. Upd, the Jak ligand, is secreted by the polar cells and establishes this gradient (denoted by arrows; discussed in Section 1.2.5.1). The most anterior cells are the anterior polar cells and the border cells. These squeeze between the anterior nurse cells and begin migrating posteriorly (illustrated here are the central polar cells (blue) surrounded by border cells (red) among the nurse cells). Border cell migration finishes at the beginning of stage 10 when they reach the anterior of the oocyte. Later, they create the micropylar pore through which sperm passes at fertilization. The next-most anterior cells form a thin layer of squamous cells (the stretched cells) that remain associated with the nurse cells until late oogenesis. The follicle cells immediately posterior to these (the centripetally migrating cells) will migrate posteriorly to the nurse cell/oocyte interface, then will migrate inward until they cover the anterior of the oocyte, where they will later produce the anterior vitelline membrane and chorion. More posterior follicle cells become increasingly columnar, and migrate posteriorly to cover only the oocyte by stage 10. During this same period of development, the oocyte nucleus migrates to the dorsal-anterior corner of the oocyte. Gurken (Grk) is secreted from that location, activates Egfr in adjacent follicle cells, and specifies them as dorsal (discussed in Section 1.2.6.5.1).

cease mitosis and become polyploid by endocycling, before chorion gene amplification takes place during stages 10–13. The transition from mitosis to endocycle is controlled by the Notch-pathway signaling from the germline. Just before follicle transition from mitosis to endocycle, germline Delta (Dl) expression increases to activate Notch in all follicle cells. Notch activation represses the expression of the CDC25 phosphatase encoded by *string*, allowing the follicle cells to exit mitosis and differentiate (Deng *et al.*, 2001; Lopez-Schier and St. Johnston, 2001).

Until stage 6, the follicle cells surrounding the cyst are relatively uniform in size and shape. During stages 7 and 8, the anterior follicle cells begin to migrate posteriorly around the enlarging oocyte (**Figure 4**). The posterior follicle cells become increasingly columnar, while those covering the nurse cells at the anterior begin to flatten and form a thin layer of squamous cells (the stretched cells). By the beginning of stage 10, most follicle cells cover the oocyte, which takes up the posterior half of the egg chamber. The oocyte nucleus has migrated to the dorsal-anterior corner of the oocyte and the dorsal follicle cells (those closest to the oocyte nucleus) become taller than those on the ventral side. Next, the anterior-most columnar follicle cells (the centripetally migrating cells) start to migrate between the nurse cells and oocyte until they cover the anterior of the oocyte, where they will produce the anterior vitelline membrane and chorion.

During stage 9, 6–8 follicle cells and the adjacent anterior polar cell (the border cells) squeeze between the anterior nurse cells and begin migrating posteriorly. Border cell migration finishes at the beginning of stage 10 when they reach the anterior of the oocyte. Here, they create the micropylar pore through which sperm passes at fertilization. The different populations of migrating follicle cells can be visualized with enhancer-trap reporter transgenes: centripetally migrating cells (P{LacW}BB127; Roth *et al.*, 1995), border cells (P{LacZ}5A7; Roth *et al.*, 1995), and stretched cells (P{LacZ}MA33; Gonzalez-Reyes and St. Johnston, 1998). The genes identified by these P-element insertions have not been characterized.

1.2.5.1. The Organizing Activity of Polar Cells

The polar cells are a signaling source that specifies different follicle cell fates through the Janus kinase (Jak) pathway. Its substrate, Unpaired (Upd), is specifically expressed in the polar cells at both poles (Xi *et al.*, 2003). Upd interacts with the cell-surface receptor Domeless (Dome) in nearby follicle cells to activate Jak (Hopscotch, Hop) and Stat (Stat92E). Without polar cells, no stalk cells are specified and the three distinct anterior follicle cell types are missing (Grammont and Irvine, 2002).

Polar cells refine the polar cell domain and induce stalk cell fate through the Jak pathway (Zhang and Kalderon, 2000; Lopez-Schier and St. Johnston, 2001; Baksa *et al.*, 2002; McGregor *et al.*, 2002). Loss of *Stat92E* or *hop* in the follicle cells blocks stalk cell specification and leads to an increase in the number of polar cells, while overexpression of *upd* causes all of the polar and stalk cell precursors to differentiate as stalk cells. Upd from the polar cells also induces a wider field of follicle cells at each pole to adopt a terminal fate (**Figure 4**; Xi *et al.*, 2003), thus separating the epithelial layer into a main body region and two terminal regions. *mirror* (*mirr*) expression can be used as a marker for main body fate since it is expressed in the main body cells, with a graded reduction toward the egg chamber poles. Ectopic *mirr* expression is observed in *hop* mutant cells regardless of position, and ectopic expression of *hop* or *upd* activates the Jak pathway and is sufficient to repress *mirr* expression. Ectopic *upd* represses *mirr* expression nonautonomously and in a graded fashion, while cell-autonomous activation of the Jak pathway, achieved by overexpressing *hop*, autonomously represses *mirr* expression. These results indicate a direct role for Jak in establishing terminal domains by repressing main body fate.

Within the anterior terminal region, graded Jak activity plays an important role in specifying the border, stretched, and centripetal follicle cells (**Figure 4**; Silver and Montell, 2001; Beccari *et al.*, 2002; Xi *et al.*, 2003). Jak activity can be measured by assessing nuclear accumulation of Stat, the Jak pathway transcriptional activator, and increasing levels are observed near the polar cells. Also, the graded expression of Jak-responsive reporters in the polar domains can be ectopically recapitulated in response to ectopic *upd* expression. At the highest levels of Jak activation, adjacent to the polar cells, Jak activity is necessary and sufficient to specify border cell fate. In addition, reducing Jak signaling reduces the adoption of border, centripetal, and stretch cell fate, while ectopic expression of *upd* or *hop* can induce ectopic adoption of these fates (Xi *et al.*, 2003). These results suggest that Upd acts as a morphogen to induce different cell fates at a distance and in a concentration-dependent manner. However, specification of stretched and centripetal cells appears to involve additional mechanisms. For instance, Grammont and Irvine (2002) have demonstrated that stretched and centripetal cells can form normally in the absence of Upd signaling. This could

be explained if other Upd-like ligands are involved (three such genes are present and functional; Hombria and Brown, 2002). Also, there are contradictory reports about the effects of *hop* and *stat92E* mutants, and therefore Jak signaling, on the specification of stretched and centripetal cells (Beccari *et al*., 2002; Xi *et al*., 2003). Denef and Schüpbach (2003) have raised the interesting suggestion that the gradient of Jak activity may be overlaid on cells with different responsiveness at different developmental stages, thus explaining these apparent contradictions, and perhaps providing a mechanism to achieve greater precision in patterning.

Loss of polar cells or Jak activity at the posterior end of the egg chamber disrupts the oocyte A–P polarity (Deng and Ruohola-Baker, 2000; Grammont and Irvine, 2002; Xi *et al*., 2003). Initially, the terminal follicle cell populations are equivalent; anterior and posterior cells that are at a similar distance from the polar cells have similar identities. In mosaics, small groups of *epidermal growth factor receptor* (*egfr*) mutant posterior cells interpret their distance from the posterior pole and autonomously adopt the appropriate anterior fate, indicating a mirror-image pre-pattern along the A–P axis (Gonzalez-Reyes and St. Johnston, 1998). This pattern is disrupted during stage 6, when Grk, secreted from the posteriorly localized oocyte, activates Egfr and specifies posterior fate in adjacent follicle cells (**Figure 4**; reviews: Nilson and Schüpbach, 1999; Lopez-Schier, 2003). Using *punt* (*put*) expression as a marker for posterior follicle cell fate, Xi *et al.* (2003) have shown that the coordinated activity of the Egfr and Jak pathways are necessary and sufficient to induce posterior follicle cell identity. Clones of cells that express activated Egfr can induce posterior fate in anterior follicle cells, but not in the main body cells. However, the coexpression of activated Egfr and Jak is sufficient to induce posterior fate in all follicle cells. Therefore, Jak activation induces competence to respond to Egfr activation in both polar domains, and localization of the oocyte nucleus determines which polar domain is specified as posterior.

1.2.5.2. Polar Cells Transmit Polarity to Adjacent Cysts

When a cyst leaves the germarium, the oocyte is always found at the most posterior position of the egg chamber. By germarial region 2B, the oocyte is specified and expresses higher levels of the adhesion molecules DE-Cadherin, α- and β-Catenin relative to the nurse cells. Prior to differentiating into the polar and stalk cells, the intercyst somatic cells face the flattened germline cyst and also express high levels of these adhesion molecules. When egg chambers or follicle cells do not express DE-Cadherin or β-Catenin, the oocyte is normally specified but is often mislocalized. Therefore, an adhesion-mediated sorting process establishes oocyte positioning (Godt and Tepass, 1998; Gonzalez-Reyes and St. Johnston, 1998; review: van Eeden and St. Johnston, 1999).

Polar cells have been implicated in oocyte localization because their loss leads to A–P polarity defects in the egg chamber, and the oocyte is often found apposing the polar cells even when the latter are not at the posterior end (Grammont and Irvine, 2002). In addition to disrupting polar cell specification (see below), *Notch* mutants cause egg chamber A–P polarity defects. In mosaics, when *Notch* is missing from the follicle cells, or *Dl* is missing from the germline, polar cells are not specified. However, stalk cells always differentiate between a mutant egg chamber and the next older wild-type egg chamber, while the stalk between the mutant follicle and the next younger follicle to the anterior is not specified, indicating that only anterior polar cells induce stalk cells (Torres *et al*., 2003). In addition, the anterior egg chamber frequently mislocalizes its oocyte, independent of genotype (Torres *et al*., 2003). These results indicate the transmission of polarity between egg chambers from posterior to anterior in the germarium. In this model, Dl is required in the germline to activate Notch and specify polar cell fate, while the anterior polar cells specify the anterior stalk through Jak signaling. The polar or stalk cells would then induce DE-Cadherin expression in the posterior follicle cells of the next younger egg chamber through an unknown mechanism, thereby orienting the oocyte at the posterior of the egg chamber.

1.2.5.3. Determining the Polar Cells

Clearly, polar cells are important organizing centers that pattern the follicular epithelium. They are specified through a complex multi-step process beginning with the subdivision of the polar-stalk lineage from the main body follicle cells. Then, localized Notch activity in this lineage represses the expression of the main body determinant *eyes absent* (*eya*), therefore allowing polar cell specification. Localized Notch activity is ensured through the localized expression of *mirror* (*mirr*) at the anterior of the germarium, but the mechanisms that localize *mirr* expression are not well understood. Mirror (Mirr) represses expression of the Notch signaling regulator Fringe (Fng), and this is thought to localize Notch activity to the polar-stalk cell lineage.

1.2.5.3.1. Epidermal growth factor receptor The mechanism that subdivides the polar-stalk cell precursors from the main body cells has not been characterized, though it might depend on an inductive signal from mature 16-cell cysts (Spradling *et al.*, 1997). Cyst encapsulation requires the function of the genes that encode the Epidermal growth factor receptor (Egfr), its ligand Gurken (Grk), and at least two additional genes, *brainiac* (*brn*), and *egghead* (*egh*) (Goode *et al.*, 1992, 1996a, 1996b; Rubsam *et al.*, 1998). Loss of *grk*, *brn*, or *egh* from the germline or *egfr* from the follicle cells leads to the production of fused follicles that are made up of multiple sets of nurse cells and oocytes surrounded by a single layer of follicle cells. These fused egg chambers are formed in the germarium because follicle cells often fail to migrate between cysts.

brn is first expressed in the germline, when the follicle cells begin to surround the cyst. The *brn* phenotype can be enhanced by reducing the dose of *egfr* or *grk*, suggesting that *brn* is required for *egfr* activation in the follicle cells, and that *egfr* activation is required for follicle cell migration during encapsulation. *brn* encodes a glycolipid-specific β1,3*N*-acetylglucosaminyltransferase (Muller *et al.*, 2002), and *egh* encodes a Golgi-located β1,4-mannosyltransferase predicted to form the precursor glycolipid for Brn (Wandall *et al.*, 2003). These enzymes function in the biosynthesis of glycolipids that might mediate extracellular signal-receptor function through direct interactions between glycolipids and receptors, including, but not limited to, Egfr.

1.2.5.3.2. Notch, Delta, and Fringe Polar cell specification is progressive, since early stage egg chambers contain at each pole an excess of cells that express polar cell markers, while by stage 4, they invariably contain only two pairs of such cells (Ruohola *et al.*, 1991). For example, the cell adhesion molecule Fasciclin III (FasIII) is first detected in all follicle cells in region 2 of the germarium (except the SSCs, Section 1.2.2). Its expression begins to restrict to the polar cell precursors by region 3 of the germarium, and is fully restricted to two cells only after the egg chamber has completely separated from the germarium.

Loss-of-function alleles of *Notch* (*N*) or *Delta* (*Dl*) cause a cyst encapsulation defect allowing polycystic fusions to accumulate in the germarium (Ruohola *et al.*, 1991). In weak *Notch*^{ts} mutants, the polar expression domain of FasIII is expanded (Goode *et al.*, 1996a), and in mosaics of strong *Notch* alleles, mutant cells, but not their neighbors, maintain FasIII expression regardless of their location (Grammont and Irvine, 2001; Lopez-Schier and St. Johnston, 2001). These results have been interpreted to suggest that Notch suppresses polar cell specification, and extra polar cells are produced in its absence. However, Notch target genes, including those of the *Enhancer of split Complex* (*E(spl)-C*), are highly expressed specifically in polar cells, confirming that Notch is active in these cells. Polar cells can also be identified by the specific expression of *neuralized* (*neur; P{lacZ}A101*) (Ruohola *et al.*, 1991), and *Notch* mutant follicle cells never express *neur* (Lopez-Schier and St. Johnston, 2001). These results indicate that *Notch* mutant cells do not differentiate as polar cells, but instead arrest as undifferentiated precursors.

Loss of *fng* also causes fusion of adjacent egg chambers. *fng* encodes a glycosyltransferase that cell-autonomously modifies the Notch receptor to potentiate Dl–Notch signaling. *Dl* is required in the germline, while *fng* and *Notch* are required in the follicle cells, for the specification of polar cell fate (Grammont and Irvine, 2001; Lopez-Schier and St. Johnston, 2001). In contrast to *Dl* and *Notch*, which are generally expressed, *fng* expression is restricted to the intercyst cells of the stage 2B germarium by *mirr* (see below), then to the polar cells and stalk cells, as they differentiate. From stages 2–6, *fng* is specifically expressed in the polar cells. Mosaic analysis indicates that *fng* is exclusively required in the polar cell-stalk cell lineage, for establishing polar cell fate, but not stalk cell fate. In fact, only two *fng*$^{+}$ cells are required to begin or end a compound egg chamber.

1.2.5.3.3. Mirror *mirror* mutant germaria are phenotypically similar to *fng*, and *mirr* expression is complementary to *fng* expression: in the germarium, *mirr* is expressed in the IGS cells and the anterior-most follicle cells, whereas *fng* is expressed in the more posterior follicle cells (Jordan *et al.*, 2000). In a young egg chamber, *mirr* is expressed in the main body follicle cells and *fng* in the polar cells and stalk cells. These complementary expression patterns are controlled by the ability of the Mirr transcription factor to repress *fng* expression. Thus, *mirr* expression must be excluded from the polar cell lineage for their specification, and *mirr* mutant ovaries likely have compound follicles because derepressed *fng* expression prevents Notch activation and polar cell specification.

The mechanisms that control *mirr* expression in the germarium are less well understood. Activation of the Jak pathway represses polar *mirr* expression in young egg chambers (Xi *et al.*, 2003), and the Jak ligand *unpaired* (*upd*) is expressed in the polar/stalk cell precursors in region 3 of the germarium

(McGregor *et al*., 2002). This suggests that Jak signaling is already active before polar cell pairs are specified, and that Jak might repress *mirr* expression in the stalk-polar cell lineage.

Since *mirr* expression in dorsal follicle cells of late-stage egg chambers depends on *grk* (Jordan *et al*., 2000), it is tempting to speculate that *grk* also regulates *mirr* expression in the germarium. However, in a *grk* hypomorphic background, early *mirr* expression seems unaffected (Jordan *et al*., 2000), suggesting that another pathway induces *mirr* expression in the IGS cells and anterior-most follicle cells. The proteins encoded by *wg* and *hh* are proposed to cooperate to activate *mirr* expression in the eye-antennal disc (Lee and Treisman, 2001), and these signals are both active within the *mirr* expression domain in the germarium (Section 1.2.2.4.3), suggesting they may have a similar function in the germarium. However, the relationships among the stem cell niche signals, *Egfr*, and the signaling mechanisms operating in the polar-stalk cell lineage have not yet been wholly explored.

1.2.5.3.4. Eyes absent Expression of *eyes absent* (*eya*) might determine main body follicle cell fate. *eya* encodes a transcription cofactor that is expressed in prefollicular cells (**Figure 4**), then is specifically turned off in the intercyst cells as these intercalate in region 2B/3 of the germarium (Bai and Montell, 2002; Torres *et al*., 2003). *eya* is not expressed in the differentiated polar cells or stalk cells. *eya* functions cell-autonomously, and its absence allows main body follicle cells to assume the polar cell fate. Ectopic expression of *eya* is sufficient to suppress normal polar cell specification, thus, *eya* expression must be repressed in the polar cells to allow their specification.

Cells not expressing *eya* are not found in *Notch* or *fng* mutant follicles. Overexpression of *fng* or a constitutively active Notch receptor is sufficient to cell-autonomously repress *eya* expression, but only within the polar-stalk lineage, and this effect is limited to the generation of one or two extra polar cells (Grammont and Irvine, 2001; Bai and Montell, 2002). Therefore, Notch signaling is required exclusively in the polar cells for repressing *eya* expression and allowing specification of polar cells, but not for the specification of the intercyst precursors of polar and stalk cells.

In addition to its role in regulating SSC proliferation and maintenance (Section 1.2.2.4.3), Hh regulates *eya* expression. Overexpression of *hh*, or loss of *hh* pathway inhibitors, is sufficient to repress *eya* expression and generate ectopic polar cells outside of the intercyst lineage (Bai and Montell, 2002). However, *hh* expression is normally limited to the terminal filament and cap cells at the anterior end of the germarium. Although the Hh signal is received at a distance by the SSCs and the prefollicle cells, there is evidence that polar cell fate can be specified, with an abnormal delay, in cells that cannot directly transduce the Hh signal (Zhang and Kalderon, 2000; Bai and Montell, 2002). This indicates the presence of other signals, acting downstream or independently of Hh, that repress *eya* expression and allow polar and stalk cell fates to be specified. Wingless is a good candidate for such a signal since it is expressed in the same cells as Hh and also affects SSC maintenance, while for reasons already discussed, the Jak–Stat pathway does not appear to be involved in polar cell specification.

1.2.6. Establishing Embryonic Polarity

Localization of maternal *gurken* (*grk*), *bicoid* (*bcd*), *oskar* (*osk*), and *nanos* (*nos*) mRNAs to the egg cortex during oogenesis is critical to embryonic axes establishment. These mRNAs are synthesized in the nurse cells, transported into the oocyte, and localized within the oocyte to their cortical destinations. Many of the genes involved in these processes were identified through mutations that disrupt egg polarity in the now famous maternal-effect lethal and female sterile screens (Nusslein-Volhard *et al*., 1987; Schüpbach and Wieschaus, 1989; Schüpbach and Wieschaus, 1991). These screens could only recover mutations that were not lethal, so although they were very successful in identifying genes required for axis determination, other genes involved in this process that are also essential for viability must have been missed. Genetic screens using germline clones promise to identify these genes, and will be important to a deeper understanding of the cell biology of axis determination (Martin *et al*., 2003).

The A–P polarity of the cyst and the oocyte is defined in the germarium (Sections 1.2.4.1 and 1.2.5.3). The oocyte localizes to the posterior of the cyst because oocyte and the posterior-most follicle cells express highest levels of DE-Cadherin. A posterior cortical domain is defined through *par* gene activity, and a posterior MTOC that nucleates MT minus ends is established between the oocyte nucleus and the posterior cortex (**Figure 2**). Posterior oocyte localization in the egg chamber is maintained through the early stages of oogenesis, and during stages 6–7, posterior follicle cell fate is induced in the follicle cells that overlay the oocyte (**Figure 4**, reviews: Nilson and Schüpbach, 1999; Riechmann and Ephrussi, 2001). This induction is

mediated by Egfr in the follicle cells, and the germline TGF-α like signal encoded by *grk*. *grk* mRNA and protein are already localized in the oocyte, when egg chambers bud from the germarium. It is controversial whether *grk* is transcribed in nurse cells and transported toward the posterior MTOC, like many other proteins and RNAs that localize in the early oocyte, or if *grk* is primarily transcribed from the oocyte nucleus (Saunders and Cohen, 1999; Thio *et al.*, 2000). Grk preferentially accumulates between the oocyte nucleus and the follicle cells adjacent to the posterior of the oocyte, from where it activates Egfr signaling (**Figure 4**), which specifies those follicle cells as posterior. The posterior follicle cells then signal back to the oocyte, to induce the cytoskeletal reorganization that is required to direct the posterior localization of *osk* and *nos* mRNAs, the anterior localization of *bcd* mRNA, and the dorsal-anterior relocalization of the oocyte nucleus and *grk* mRNA.

1.2.6.1. Oocyte Cytoskeletal Polarity and *oskar* Localization

Major cytoskeletal reorganization occurs during mid-oogenesis (stages 7–8), after which the posterior MTOC is no longer detected (review: Riechmann and Ephrussi, 2001). In later stages, cytoskeletal polarity has been inferred from the localization in oocytes of reporter proteins whose properties are known in other polarized cells, such as epithelial cells or neuronal axons. Specifically, Nod : β-Gal is a microtubule minus-end reporter that is localized anteriorly, while Kinesin : β-Gal is a microtubule plus-end reporter that localizes posteriorly in stage 8–9 egg chambers (review: Riechmann and Ephrussi, 2001). Posterior localization of *osk* mRNA, which also occurs during stage 8–9, requires the *kinesin heavy chain* (*khc*) gene, which encodes a component of the conventional Kinesin motor complex. In addition, posterior *osk* localization is disrupted by MT depolymerization or in mutants that disturb oocyte polarity (e.g., *grk* mutants). The simplest model to account for these results is that *osk* mRNA is localized by Kinesin on a highly polarized MT cytoskeleton oriented with its minus ends at the anterior and its plus ends at the posterior. In further support of this model, cytoplasmic Dynein, the oocyte's minus-end directed motor, is required for anterior localization of *bcd* mRNA (Duncan and Warrior, 2002; Januschke *et al.*, 2002).

Dynein function is mediated by the multi-protein Dynactin complex, made up of p150^{Glued}, p50 Dynamitin (Dmn), and Lissencephaly-1 (Lis-1). Overexpressing Dmn causes Dynein to dissociate from Dynactin, and disrupts anterior *bcd* localization (Brendza *et al.*, 2002; Duncan and Warrior, 2002; Januschke *et al.*, 2002).

However, several experimental observations are not readily accommodated by this model. One is the ability of MT minus-ends and *osk* mRNA to associate with most of the oocyte cortex (Shulman *et al.*, 2000; Cha *et al.*, 2002; Vaccari and Ephrussi, 2002). After cytoskeletal reorganization, the bulk of the MT network accumulates at the anterior cortex of the oocyte, creating a higher density of MTs in the anterior of the oocyte than the posterior (**Figure 2**; Theurkauf *et al.*, 1992; Clark *et al.*, 1994). Microtubule nucleation is mediated by the γ-Tubulin Ring Complex (γTuRC), which associates with centrosomes and the minus-ends of MTs (Moritz *et al.*, 2000). In stage 10 oocytes, components of γTuRC are uniformly distributed along the entire oocyte cortex, suggesting that the cortex is uniform in its capacity to nucleate MT minus-ends (Cha *et al.*, 2002). Consistent with this observation, loss of *khc* disrupts posterior *osk* mRNA localization, but instead of localizing diffusely or at the center of the oocyte, *osk* mRNA associates with the anterior and lateral cortices (Cha *et al.*, 2002). These results indicate that most of the oocyte cortex can support *osk* localization, and that plus-end directed transport normally carries *osk* away from the cortex except at the MT-poor posterior pole.

Par-1 localization to the posterior cortex might account for the low MT density observed at the posterior pole (Shulman *et al.*, 2000; Vaccari and Ephrussi, 2002). Loss of *par-1* leads to the nucleation of MT minus-ends along the entire cortex of mid-stage oocytes, resulting in abnormal localization of *osk* mRNA to the center of the oocyte together with the MT plus ends (Riechmann *et al.*, 2002; Shulman *et al.*, 2000; Tomancak *et al.*, 2000). Par-1 acts in a conserved pathway that regulates cell polarity and MT dynamics, and may function similarly to its mammalian orthologs, the microtubule-affinity regulating kinases (MARKs). MARKs phosphorylate microtubule-associated proteins (MAPs) and disrupt their binding to MTs. MAPs normally bind along the length of the MTs to stabilize them, so MARK activity destabilizes MTs (Drewes *et al.*, 1997; Ebneth *et al.*, 1999). A similar function could destabilize posterior MTs in the *Drosophila* oocyte and allow posterior localization of *osk* mRNA.

1.2.6.2. Dynein and Kinesin: Dueling Motors

Although Dynein is the major minus-end directed MT motor, both Dynein heavy chain : β-Gal (Dhc : β-Gal), p150^{Glued}, and Dmn are enriched at the posterior pole (McGrail and Hays, 1997; Wilkie

and Davis, 2001; Duncan and Warrior, 2002). Additionally, although Kinesins are generally plus-end directed motors and concentrate at the posterior pole, in germline clones mutant for *khc*, anterior localization of *bcd* and *grk* mRNA and posterior *osk* localization are all disrupted (Brendza *et al.*, 2000; Duncan and Warrior, 2002; Januschke *et al.*, 2002). Thus, the distribution of both motor complexes is similar, and *khc* is required for transport to many different locations in the oocyte. If MT plus-ends are pointed posteriorly, the requirement for Kinesin in anterior transport, and the posterior localization of Dhc : β-Gal must be indirect. Importantly, in *khc* mutant egg chambers, Dhc : β-Gal moves to the anterior cortex, indicating that Kinesin normally relocates Dynein from the anterior cortex to the posterior (Brendza *et al.*, 2000, 2002; Duncan and Warrior, 2002; Januschke *et al.*, 2002). These results suggest that Kinesin and Dynein are both components of the same complex, and that they might cooperate to recycle one another for renewed rounds of cargo loading and transport.

Motor recycling could play an essential role in the efficient transport of a population of small cargoes. In this model, cargoes associate with a complex that includes two opposing motors and can move efficiently in one direction depending on the regulatory state of the opposing motors (Duncan and Warrior, 2002; Gross *et al.*, 2002; Januschke *et al.*, 2002). The dual motor model implies that the cargo to be localized contains proteins capable of directing intracellular transport, so understanding how mRNAs are packaged into transport-competent complexes is important.

1.2.6.3. RNA Recognition Complexes

1.2.6.3.1. Posterior *oskar* localization *Cis*-acting elements in the *osk* mRNA 3′ untranslated region (3′UTR) are essential for *osk* mRNA transport (Ephrussi and Lehmann, 1992; Kim-Ha *et al.*, 1993). *Oskar* mRNA travels from the nurse cells to the posterior of the oocyte as part of a ribonucleoprotein (RNP) complex, that includes at least two RNA binding proteins, Staufen (Stau) and Tsunagi (Tsu), that control the localization and translation of *osk*. Until its posterior localization, *osk* translation is repressed by several trans-acting factors that bind to its 3′UTR (Kim-Ha *et al.*, 1995; Gunkel *et al.*, 1998; Lie and Macdonald, 1999). Repressing *osk* translation during transport from the nurse cells to the oocyte requires Me31B, a DEAD-box RNA helicase (Nakamura *et al.*, 2001). The RNA-binding protein Bruno (Bru) is also required for repression of unlocalized *osk* in the oocyte, although complete repression also requires Apontic (Apt) and p50 (review: Johnstone and Lasko, 2001). Mutations in *cup* block posterior *osk* mRNA localization, and also allow translation of unlocalized *osk*, indicating that Cup is an important link between *osk* localization and translational control (Wilhelm *et al.*, 2003; Nakamura *et al.*, 2004). The mechanisms that relieve *osk* translational repression upon localization remain elusive, but they involve a de-repressor element in the *osk* 5′UTR (Gunkel *et al.*, 1998), Stau (Micklem *et al.*, 2000), the eIF2C-related protein Aubergine (Aub; Wilson *et al.*, 1996), and Orb. In particular, Orb maintains the length of the *osk* poly-A tail to enhance *osk* translation (Lantz *et al.*, 1992; Christerson and McKearin, 1994; Castagnetti *et al.*, 2000).

While in normal development *osk* translation requires posterior localization of its mRNA, these two processes can be uncoupled experimentally. For example, treatment of ovaries with MT depolymerizing drugs results in the ectopic association of *osk* mRNA to the oocyte cortex, and a broad cortical accumulation of Osk and Vas, indicating that most of the oocyte cortex can accommodate the first steps of pole plasm assembly and support *osk* translation (Cha *et al.*, 2002). Similarly, centrally mislocalized *osk* mRNA is translated in *encore* or *par-1* mutant egg chambers (Tomancak *et al.*, 2000; Van Buskirk *et al.*, 2000), or when *laminin A* (Deng and Ruohola-Baker, 2000) mutant posterior follicle cell clones are produced.

Several lines of evidence suggest that the nuclear history of *osk* mRNA can determine its fate in the cytoplasm. The nuclear shuttling proteins Mago Nashi (Mago), Barentsz (Btz), and Tsunagi (Tsu) are required for posterior *osk* localization. In *btz* mutants or in hypomorphic alleles of *mago* or *tsu*, *osk* mRNA fails to accumulate at the posterior, and instead localizes to the anterior margin (Newmark and Boswell, 1994; Micklem *et al.*, 1997; Hachet and Ephrussi, 2001; Mohr *et al.*, 2001; van Eeden *et al.*, 2001). Mago, Btz, and Tsu are components of the exon-junction complex (EJC), and remain with the mRNA after its export from the nucleus, marking the site of intron removal. Although Mago and Tsu are predominately nuclear, while Btz associates with the nuclear envelope, all three proteins shuttle and localize with *osk* mRNA and Stau at the posterior of stage 9 oocytes. These results are consistent with the function of Mago, Btz, and Tsu as components of the *osk* mRNA transport complex. The binding of EJC proteins to *osk* mRNA in the nucleus is thought to imprint the mRNA, and may be a critical step in its posterior targeting (Hachet and Ephrussi, 2001).

Observations of injected *osk* mRNA suggest an additional MT-independent step in *osk* localization, suggesting that cytoplasmic flows or vesicle trafficking are an important final stage in carrying *osk* to the posterior (Glotzer *et al.*, 1997; Dollar *et al.*, 2002). Once *osk* mRNA reaches the posterior of the oocyte, it is stably anchored and translated to allow the assembly of polar granules (Section 1.2.7.1). Actin-dependent anchoring of *osk* mRNA at the posterior has been inferred from the loss of *osk* localization in *tropomyosin II* and *moesin* mutants, and the partial release of *osk* from the posterior upon Actin depolymerization (Erdelyi *et al.*, 1995; Cha *et al.*, 2002; Jankovics *et al.*, 2002; Polesello *et al.*, 2002). Osk protein is also required to anchor its own mRNA at the posterior, since *osk* mRNA is not maintained at the posterior in protein-null *osk* mutants (Ephrussi *et al.*, 1991; Kim-Ha *et al.*, 1991).

1.2.6.3.2. Anterior *bicoid* localization The *bcd* transcripts are also modified prior to their transport into the oocyte from adjacent nurse cells such that they specifically associate with the anterior cortex (Cha *et al.*, 2001). When injected directly into the oocyte, *bcd* mRNA forms particles that localize to the nearest anterior or lateral cortical surface. Only after *bcd* mRNA has been injected into the nurse cell cytoplasm, withdrawn, and then injected into the oocyte, does it specifically associate with the anterior cortex. Endogenous *bcd* mRNA is found by stage 9 in the nurse cells in large perinuclear clusters of mRNA and proteins (mRNPs). Exuperantia (Exu) protein is also a component of these clusters, which are transported into the oocyte. *bcd* mRNA then localizes to the anterior cortex between stages 10 and 12. In *exu* mutants, the perinuclear clusters fail to form and *bcd* mRNA moves into the oocyte but does not localize to the anterior cortex. Injection of labelled *bcd* mRNA into the nurse cells allows the formation of large (0.5–1 μm) Exu-containing mRNPs which are capable of localizing specifically to the anterior (Cha *et al.*, 2001).

Exhaustive deletion analyses of the *bcd* 3′UTR has identified a minimal localization element that is sufficient for nurse cell to oocyte transport and anterior cortical localization (Macdonald and Kerr, 1997, and references therein). Using a gel-mobility shift assay, Arn *et al.* (2003) have identified a multiprotein complex that binds to the minimal *bcd* mRNA localization signal. It includes a member of the Kinesin family of motor proteins, Nod, and at least four proteins with RNA binding motifs, Modulo (Mod), Swallow (Swa), Smooth (Sm), and Poly-A binding protein (Pabp). Of these, only Swa had been previously implicated in *bcd* localization. In *mod* mutant egg chambers, *bcd* mRNA is often abnormally associated with the lateral cortex of the oocyte. Furthermore, *bcd* mRNA injected into *mod* mutant nurse cells rarely forms RNP particles, and those that do form usually fail to localize to the anterior cortex.

Swa is required for the anterior localization and anchoring of *bcd* mRNA, but is not required for the localization of *bcd* from the nurse cells into the oocyte (Schnorrer *et al.*, 2000). Swa is localized to the anterior, and this depends on MTs but not Exu or *bcd* (Stephenson and Mahowald, 1987; Stephenson *et al.*, 1988). Swa includes an RNA binding motif, and a coiled-coil domain that interacts with Dynein light chain (Dlc). Since disrupting Dynein function causes frequent defects in *bcd* mRNA localization (Duncan and Warrior, 2002; Januschke *et al.*, 2002), and mutations that block the association of Swa with Dlc also block anterior *bcd* localization, Swa appears to act as an adaptor between the Dynein motor complex and *bcd* mRNA (Berleth *et al.*, 1988; St. Johnston *et al.*, 1989; Schnorrer *et al.*, 2000). Anterior *bcd* localization is also diffuse in *khc* mutants, suggesting that repeated cycles of posterior to anterior transport are required to maintain *bcd* localization (Januschke *et al.*, 2002; see dual motor model, Section 1.2.6.2).

A final redistribution of *bcd* mRNA is presumed to occur at the end of oogenesis since its distribution in stage 12 oocytes differs slightly from that in freshly laid eggs (St. Johnston *et al.*, 1989). In late-stage oocytes, *bcd* is cortically localized to an anterior cap, while in very early embryos, it does not appear specifically bound to the cortex and is often located slightly dorsally. Stau binds to the *bcd* 3′UTR and, in the absence of *stau* function, *bcd* is localized normally during oogenesis, but becomes partially delocalized in the embryo, suggesting that Stau mediates this late *bcd* mRNA localization step (St. Johnston *et al.*, 1989; Ferrandon *et al.*, 1994).

1.2.6.4. Nurse Cell-Oocyte Cytoplasmic Transfer and Late-Localizing mRNAs

The later stages of oogenesis (stages 8–14) are marked by a 100-fold increase in the protein content of the oocyte. This is accomplished by the synthesis and uptake of yolk proteins, and an Actin-dependent contraction of the nurse cells that results in the bulk transfer of nurse cell cytoplasm into the oocyte (see also **Chapter 1.3**; Gutzeit, 1986). This process of cytoplasmic transfer is often referred to as "dumping" for simplicity. Most of the nurse cell cytoplasm, which is rich in RNA and protein, ribosomes, lipid droplets, and mitochondria, is transferred through the ring canals into the oocyte

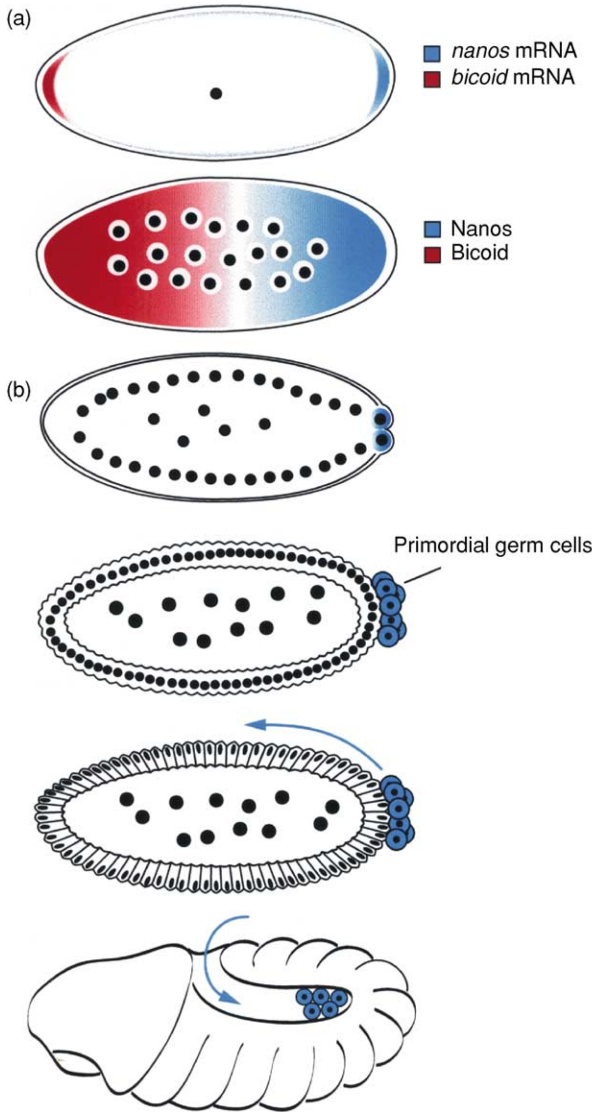

Figure 5 Embryonic Anterior–posterior polarity and primordial germ cell (PGC) specification. (a) Maternal gradients of Bicoid (Bcd) and Nanos (Nos) are established at opposite poles of the postfertilization embryo (discussed in Section 1.2.6.5) These proteins establish an anterior-to-posterior gradient of the Hunchback (Hb) transcription factor, a morphogen whose local concentration defines the position of blastoderm nuclei along the anterior–posterior (A–P) axis. Zygotic *hb* transcription is activated in a concentration-dependent manner by an anterior-to-posterior gradient of Bcd, and *hb* translation is repressed by a posterior-to-anterior gradient of Nos, producing a single anterior-to-posterior Hb gradient. Bcd also establishes a posterior-to-anterior gradient of the transcription factor Caudal (Cad), by repressing translation of *cad* mRNA in anterior regions. (b) The germline is the first distinct cell lineage established in the *Drosophila* embryo. During early syncytial divisions, nuclei form an ellipsoid array that expands from the interior of the embryo to its periphery, and during nuclear cycle 9, a few nuclei at the posterior pole contact the posterior pole, protrude, and form pole buds (top panel). Pole buds divide twice, cellularize, then the PGCs divide asynchronously to form 30–35 germ cells at the embryonic posterior (second panel from top). The PGCs then cease dividing. As the germ band extends dorsally and anteriorly during gastrulation, the posterior midgut (PMG) invaginates and the PGCs are carried into the PMG lumen (third and fourth panels).

during stages 10 and 11. Several well-characterized genes including *chickadee* (*chic*) (Cooley *et al.*, 1992), *quail* (Mahajan-Miklos and Cooley, 1994), and *singed* (*sn*) (Paterson and O'Hare, 1991), and structural components of ring canals (Section 1.2.3.1), affect the transfer of nurse cell contents into the oocyte. The oocytes in these mutants are only about one-half of wild-type size because nurse cells fail to dump their contents into the oocyte. In *chic* mutants, the nurse cell Actin filaments fail to polymerize during late stage 10. *chic* encodes Profilin, a protein that binds Actin and phospholipids, suggesting a role in anchoring microfilaments to membranes. The *singed* gene encodes a Fascin-related protein, and *quail* encodes a Villin-related protein; both of these proteins are thought to cross-link Actin filaments to form bundles.

In the oocyte, parallel arrays of microtubules assemble next to the oocyte cortex just prior to nurse cell dumping (Theurkauf *et al.*, 1992). These subcortical microtubules are required for the rapid circular flow of the oocyte cytoplasm called ooplasmic streaming, which begins during mid-oogenesis and continues until stage 13 (Gutzeit, 1986). Ooplasmic streaming is thought to complete the recruitment of macromolecules to the cortex (Theurkauf, 1994b). Cappuccino (Capu), Spire (Spir), and Profilin are required to repress ooplasmic streaming, and in their absence, premature streaming disrupts *osk*, *nos*, and *grk* mRNA localization (reviews: Manseau *et al.*, 1996; Mahowald, 2001). Both Spir, a putative G-Actin binding protein, and Capu, a Formin homology protein, have been implicated in Actin cytoskeletal dynamics (review: Hudson and Cooley, 2002). Their phenotypes, and the induction of MT-based ooplasmic streaming after Actin depolymerization, strongly suggest that the Actin and MT-based cytoskeletons are functionally interconnected.

1.2.6.4.1. Posterior *nanos* localization Localization of *nos* mRNA to the posterior of the oocyte ensures sufficient localized Nos translation to direct abdominal development and ensures the incorporation of *nos* RNA into the pole cells (**Figure 5**; Wang and Lehmann, 1991; Gavis *et al.*, 1996; Wilhelm *et al.*, 2000). *Nanos* is one of a group of late-localizing RNAs, including *germ cell-less* (*gcl*), and *polar granule component* (*pgc*), that repress transcription in the embryonic germ cells (Section 1.2.7.3; Gavis and Lehmann, 1992; Jongens *et al.*, 1992; Gavis

et al., 1996; Nakamura *et al.*, 1996). Posterior localization of these mRNAs depends on the prior establishment of polar granules at the posterior pole of the oocyte (Section 1.2.7.1). In the absence of polar granule assembly (e.g., in *osk* and *vas* mutants), *nos* mRNA remains unlocalized and its translation is repressed, so the resulting embryos fail to develop abdominal segments (Gavis and Lehmann, 1994; review: Mahowald, 2001).

Starting at stage 11, the oocyte becomes impermeable to whole-mount immunolabelling, so studies of molecular localization in these final stages of oogenesis have been hindered by the need to section or manually remove the chorion and vitelline membrane. To overcome this limitation, Forrest and Gavis (2003) have fluorescently tagged *nos* mRNA *in vivo* in order to visualize its localization in real time. They found that nurse cell dumping is required to drive *nos* mRNA into the oocyte (Forrest and Gavis, 2003). Once in the oocyte, ooplasmic streaming increases the efficiency of *nos* transfer to the posterior, but this is not absolutely necessary. Actin filaments maintain *nos* mRNA, associated with the polar granules at the posterior cortex, which detach from the cortex and are swept away as an aggregate when the Actin filaments are disrupted (Lantz *et al.*, 1999; Forrest and Gavis, 2003).

Posterior *nos* localization is inefficient, as only 4% of the total *nos* mRNA pool is found at the posterior of the embryo (Bergsten and Gavis, 1999). Translational repression of unlocalized *nos* mRNA is mediated by a 90-nucleotide translational control element (TCE) in the *nos* 3′UTR, which is bound by a multi-protein complex that includes the RNA-binding protein Smaug (Smg) (Smibert *et al.*, 1996, 1999; Dahanukar *et al.*, 1999; Crucs *et al.*, 2000). Smg function requires an interaction with the eIF4E-binding protein Cup, which mediates an indirect interaction between Smg and eIF4E (Nelson *et al.*, 2004). Cup blocks the binding of the translation initiation factor eIF4G to eIF4E, so Smg represses *nos* translation by blocking eIF4G recruitment (Nelson *et al.*, 2004). Since Smg and Osk can interact directly, posteriorly localized Osk may capture posterior *nos* mRNA and release Smg-mediated translational repression (Dahanukar *et al.*, 1999). Posterior localization of *nos* mRNA requires recognition of multiple sequence elements within a 540 nucleotide localization signal in the *nos* 5′UTR that is distinct from, yet overlaps, the TCE (Gavis *et al.*, 1996). Based on their ability to genetically separate the translational repression and localization functions of these overlapping elements, Crucs *et al.* (2000) suggest that translational activation of *nos* results when Smg binding is prevented by the direct interaction of localization factors with *nos* 5′UTR sequences.

1.2.6.5. Embryonic Anterior/Posterior Polarity

In the postfertilization embryo, positional information along the A–P axis is defined by the local concentration of the Hunchback (Hb) protein, which is highest at the anterior pole and absent from the posterior pole (reviews: Nusslein-Volhard, 1991; Riechmann and Ephrussi, 2001). Hb fits the classic definition of a morphogen (see **Chapters 1.8** and **1.9**), as it directly defines different cell fates at a distance and in a concentration-dependent manner. The Hb gradient is generated through the antagonistic activities of the maternal-effect genes *bcd* and *nos* (**Figure 5**). *bicoid* mRNA, tightly localized to the anterior pole of the embryo, encodes a transcription factor that patterns the head and thorax. Bcd acts as a transcriptional activator of *hb* (reviews: St. Johnston and Nusslein-Volhard, 1992; Rivera-Pomar *et al.*, 1995), and represses the translation of *caudal* (*cad*) mRNA in the anterior of the embryo (Dubnau and Struhl, 1996; Rivera-Pomar *et al.*, 1996; Niessing *et al.*, 2002). Like Hb, Cad is a transcription factor that activates expression of zygotic segmentation genes, such as *knirps* (*kni*) and *giant* (*gt*), which are required for posterior development (Schulz and Tautz, 1995) in a concentration-dependent manner. *nos* mRNA, localized to the posterior pole of the oocyte, encodes an RNA-binding protein that determines the primordial germ cells (Section 1.2.7) and the abdomen. Zygotic *hb* expression is activated in a concentration-dependent manner by an anterior-to-posterior gradient of Bcd, and *hb* translation is repressed by a posterior-to-anterior gradient of Nos, producing a single anterior-to-posterior Hb protein gradient.

1.2.6.6. Dorsal–Ventral Polarity

1.2.6.6.1. Dynamic *gurken* localization In *grk* or *egfr* mutants, both the oocyte and egg become ventralized, because Egfr activity specifies a dorsal fate (review: Nilson and Schüpbach, 1999). Egfr is uniformly expressed in the somatic follicle cells and its activity is restricted by the strict subcellular localization of Grk, and by the feedback mechanisms outlined below. Localization of *grk* RNA and protein changes dramatically when the oocyte cytoskeleton is reorganized. Grk is closely associated with the oocyte nucleus, and D–V polarity is first apparent at about stage 8, when the oocyte nucleus and Grk localize to the future dorsal-anterior corner of the oocyte (**Figures 4** and **6a**). During cytoskeletal reorganization, *grk* mRNA first localizes around the oocyte's anterior cortex, then concentrates dorsally

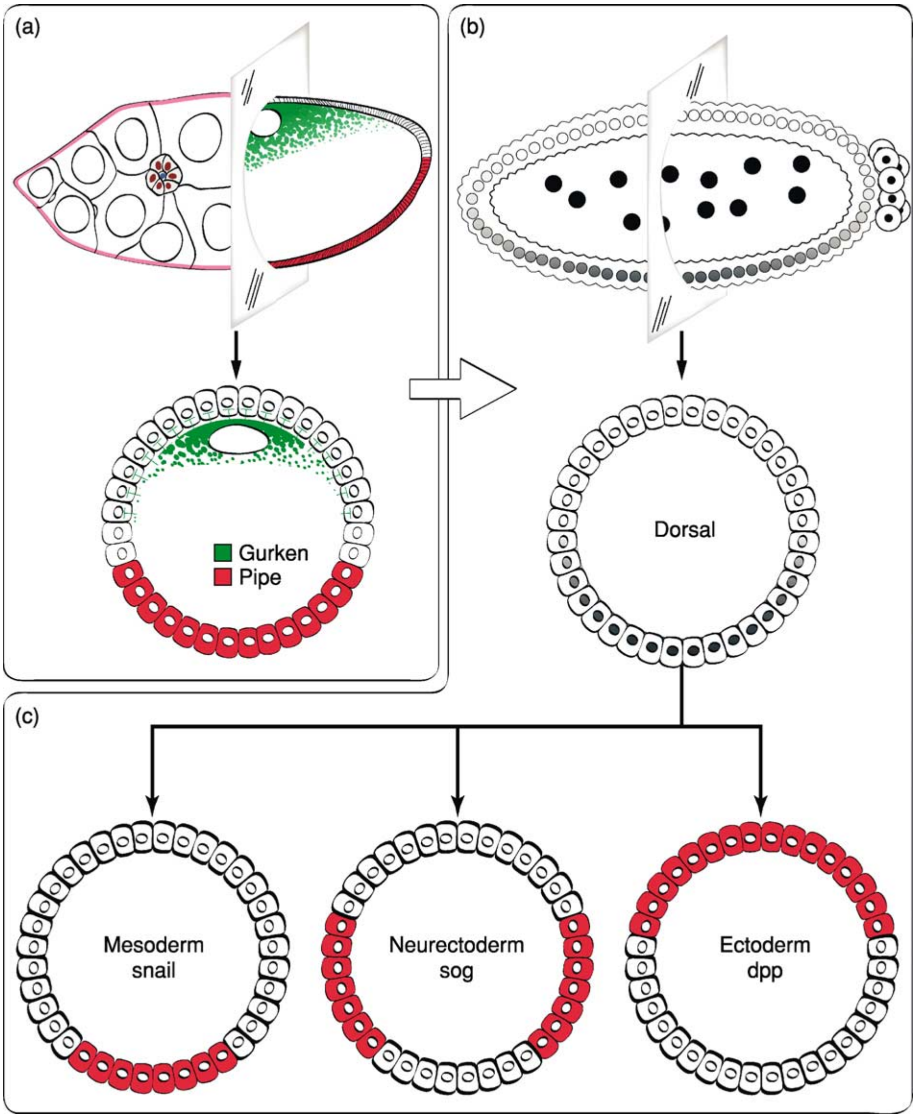

Figure 6 Localized Pipe expression in the ovary establishes dorsal–ventral polarity in the embryo. (a) In the stage-10 egg chamber, Gurken (Grk), an Egfr ligand, is restricted to the anterodorsal corner of the oocyte, and Pipe is expressed only in the ventral follicle cells (discussed in Section 1.2.6.6.2). (b) Pipe-modified ECM proteins are thought to locally initiate a proteolytic cascade that activates the Toll (Tl) receptor on the ventral surface of the now-fertilized egg (discussed in Section 1.2.6.6.4). Nuclei that migrate into ventral regions, where Tl is active, accumulate Dorsal, an NF-κB type transcription factor, while in dorsal regions, Dorsal is sequestered in the cytoplasm and is thus inactive. Nuclear import of the Dorsal protein occurs in a ventral to dorsal gradient (depicted as degrees of shading of the round nuclei) and is restricted to cells in the ventral 40% of the embryo. (c) Different concentration thresholds of nuclear Dorsal initiate the differentiation of the mesoderm, neurectoderm, and mesectoderm by activating expression of *snail* (*sna*), *short gastrulation* (*sog*), *decapentaplegic* (*dpp*) and other genes (discussed in Section 1.2.6.6.4).

between the oocyte nucleus and the overlying follicle cells. The position of the oocyte nucleus defines the new site of *grk* mRNA and protein accumulation, so the critical first step in generating D–V polarity is nuclear migration.

The nature of the asymmetry that targets oocyte nuclear migration is not fully understood, but it relies on the first Grk signal to the posterior follicle cells. Unexpectedly, the oocyte nucleus and *grk* mRNA localize normally in *par-1* hypomorphs, that allow uniform cortical MT nucleation, indicating that an anterior-to-posterior concentration gradient of MTs is not required for oocyte migration (Shulman *et al*., 2000; Vaccari and Ephrussi, 2002). However, other indicators suggest that MT polarity is important. Stable nuclear positioning and *grk* localization requires microtubules, and both Dynein and Kinesin I (Koch and Spitzer, 1983; Roth *et al*., 1999; Saunders and Cohen, 1999; Guichet *et al*., 2001). In addition, mutations affecting the

Dynein-interacting proteins Bic-D and Lis-1 are associated with mispositioning of the oocyte nucleus (Liu *et al.*, 1999; Swan *et al.*, 1999). Disrupting Dynein function by overexpressing Dmn allows the nucleus to leave the cortex during, or after localization, indicating an important function for the Dynein motor complex in cortical anchoring of the oocyte nucleus (Duncan and Warrior, 2002; Januschke *et al.*, 2002).

Dynein–dynactin complexes accumulate around the nucleus in a MT-dependent manner (Januschke *et al.*, 2002), suggesting that the nucleus may have its own perinuclear cytoskeleton that directs anterior-dorsal transport. Supporting this are observations indicating that a scaffold of MTs, or a MT cage, surrounds the oocyte nucleus (Theurkauf 1992), and that treatments which disrupt the cage also disrupt *grk* localization (Duncan and Warrior, 2002; Januschke *et al.*, 2002). For example, Dmn overexpression causes the cage to disappear, and this is associated with diffusion of *grk* mRNA and protein from the D-A corner, even when the nucleus is normally positioned. Grk protein becomes anterior or dispersed, but is not able to specify dorsal fate, leading to the production of ventralized eggs. This suggests that Dynein is additionally required for Grk protein transport to the oocyte cell membrane (Januschke *et al.*, 2002). Recent analysis of *grk* mRNA localization also suggests the presence of a special MTOC at the nucleus as a requirement for dorsal-anterior transport (MacDougall *et al.*, 2003). When labelled *grk* mRNA is injected into the oocyte, it forms particles that generally move toward the oocyte anterior, then appear to change direction and move dorsally. MacDougall *et al.* (2003) suggest that *grk* mRNA might be transported toward the minus ends of a MT skeleton that emanates from the oocyte nuclear cage. However, this model implies an as yet unclear mechanism to distinguish subpopulations of MTs.

Deletion analysis of *grk* indicates the presence of multiple *cis*-acting sequences required for *grk* mRNA transport into the oocyte (Thio *et al.*, 2000), but no *trans*-acting factors required for its early transport have been identified. The 3′UTR of *grk* mRNA, and two *trans*-acting factors, K10 and Squid (Sqd), are required for the movement of *grk* mRNA from the anterior cortex to the D-A of the oocyte (Kelley, 1993; Neuman-Silberberg and Schüpbach, 1993; Serano and Cohen, 1995; Thio *et al.*, 2000). K10 can directly interact with Sqd, which encodes a heterogenous nuclear RNA-binding protein (hnRNPA1 or Hrp40), that binds to the *grk* 3′UTR and regulates both *grk* localization and translation (Norvell *et al.*, 1999). In *K10* or *sqd* mutants, *grk* mRNA is consistently mislocalized and translated along the entire anterior cortex of the oocyte, leading to the production of severely dorsalized eggs. *sqd* produces three alternatively spliced transcripts that produce three protein isoforms with nonidentical functions. Of these, SqdS is localized within both the nurse cell and oocyte nuclei, and is the only Sqd isoform that is sufficient to both localize *grk* mRNA and rescue the dorsalized phenotype of *sqd* mutants (Norvell *et al.*, 1999). Since *sqd* encodes a nuclear shuttling protein, it may connect the nuclear export and MT-dependent localization of *grk* mRNA, analogous to the role of the exon junction complex in *osk* mRNA localization (Section 1.2.6.3.1). In support of this model, although naked (protein-free) pair rule transcripts fail to localize following injection into a blastoderm-stage embryo, pre-incubating these transcripts with any of the Sqd isoforms is sufficient to promote their MT-dependent apical localization (Lall *et al.*, 1999).

In addition to the *spindle* (*spn*) class mutations (Section 1.2.4.1.3), several other genes have been implicated in regulating *grk* translation, but their mechanisms of action remain uncharacterized. *aubergine* (*aub*) was originally identified by mutations that cause ventralized eggs, and loss of *aub* reduces *grk* translation (Schüpbach and Wieschaus, 1991; Wilson *et al.*, 1996). The weakest *orb* allele, orb^{mel}, is associated with reduced *grk* translation, suggesting that Orb may regulate *grk* translation by maintaining its poly-A tail length (Chang *et al.*, 2001). In addition to regulating *osk* translation, Bru may also suppress *grk* translation (Filardo and Ephrussi, 2003). While the *grk* mRNA expression pattern appears normal in *arrest* (*aret*) mutants (confusingly, *arrest* encodes Bru), there is some reduction in Grk protein. Although *arrest* mutants have only a mild effect on dorsal–ventral patterning, they can be strongly enhanced by a reduction in *grk* dose. Using the *grk* 3′UTR as a probe, UV-cross-linked complexes that are immunoprecipitated with anti-Bru include *grk* mRNA, thus suggesting that Bru may regulate *grk* translation directly, similar to its regulation of *osk*. This conclusion, however, does not explain the observation that phenotypes caused by ectopic Bru can be suppressed completely by overexpressing the *osk* 3′UTR. Finally, the Grk protein levels are reduced in *enc* mutants, suggesting that Enc may also influence *grk* translation or protein stability (Hawkins *et al.*, 1996, 1997).

1.2.6.6.2. Egfr directly represses *pipe* expression Localized Egfr activity in ventral follicle cells (**Figure 6**) has two distinct consequences: (1) the restriction of *pipe* expression to ventral follicle cells

to establish embryonic polarity, and (2) the specification of dorsal follicle cell fates that pattern the eggshell. Loss-of-function and ectopic expression data indicate that *pipe* is both necessary and sufficient to induce embryonic ventral fates (Nilson and Schüpbach, 1998; Sen *et al*., 1998). *pipe* is the only gene in the *dorsal* pathway with a ventrally restricted expression pattern, supporting a role in transferring D–V information from the ovary to the embryo. Follicle cells without activated Egfr take up the default ventral follicle cell fate and express *pipe* (Nilson and Schüpbach, 1998; Sen *et al*., 1998). In follicle cell mosaics, *ras* or *Raf* mutant cells that cannot transmit the Egfr signal express *pipe*, but their wild-type neighbors do not (James *et al*., 2002; Peri *et al*., 2002). Therefore, Egfr directly restricts *pipe* expression to the ventral follicle cells.

How Egfr is activated in ventral follicle cells is unclear, as Grk is restricted to an anterior-dorsal domain. Either Grk is secreted and acts as a long-range signal, or a different Egfr ligand is involved. Spitz (Spi), another Egfr ligand, is an obvious candidate as ectopic Spi activity is sufficient to repress *pipe* expression in ventral follicle cells (Peri *et al*., 2002). Spi activity is regulated by the Rhomboid (Rho) protease, which cleaves Spi in the Golgi, allowing its secretion (Urban *et al*., 2001; Wasserman and Freeman, 1998). Grk and Dpp cooperate to activate *rho* expression in the dorsal-anterior follicle cells, and Rho activates Spi secretion from these cells (Twombly *et al*., 1996; Peri and Roth, 2000). These results are consistent with a role for Spi, i.e., by acting as a secondary signal downstream of Grk, in expanding the domain of Egfr activity to a broad dorsal-anterior zone (Wasserman and Freeman, 1998). However, large dorsal clones that are mutant for *rho*, and therefore do not secrete Spi, also do not misexpress *pipe*, as would be expected if Spi repressed *pipe* in dorsal cells that are too far away to directly receive the Grk signal. So, although ectopic Spi activity is sufficient to repress *pipe* expression ventrally, it is not required to repress *pipe* dorsally. These results support a direct role for Grk in specifying dorsal fate at a distance, without requiring secondary signaling events.

The homeodomain transcription factor Mirr is expressed in response to Grk in dorsal anterior cells (Jordan *et al*., 2000; Zhao *et al*., 2000). Loss of *mirr* in mosaics leads to variable ventralization defects in the eggshell, suggesting a role in defining dorsal fate. Ectopic *mirr* expression is sufficient to repress ventral *fng* and *pipe* expression, suggesting that *mirr* might act through *fng*, and by implication the Notch signaling pathway, to repress *pipe* expression in dorsal cells (Jordan *et al*., 2000; Zhao *et al*., 2000). However, loss of *mirr* or *fng* from dorsal or ventral cells has no effect on *pipe* expression (Tran and Berg, 2003). While the role of *fng* in this process remains to be clarified, the effects of ectopic dorsal *mirr* on *pipe* expression are likely mediated through Spi and Egfr, although independently of Grk. Since ectopic *mirr* is sufficient to induce *rho* expression in ventral cells, *mirr* may normally act downstream of Egfr to activate dorsal anterior expression of *rho*, thereby affecting eggshell patterning but not embryonic patterning.

1.2.6.6.3. Refining Egfr activity A predicted consequence of the Spi positive feedback loop is that without refinement, the ensuing signal amplification would spread ventrally. Ventral broadening of Egfr activity appears to be limited by several independent means, including general repression of Egfr activity by Cbl, and Egfr-dependent expression of the *egfr* repressors Argos (Aos), Kekkon (Kek), and Sprouty (Sty), which act in negative feedback loops to refine Egfr activity (review: Leevers, 1999).

The highest level of Egfr activity occurs along the dorsal midline and depends on the Spi positive feedback loop (Wasserman and Freeman, 1998). *argos* expression is induced in these cells, and Aos is secreted, diffuses locally, and directly inhibits Egfr activity along the dorsal midline, thereby refining Egfr activity to two lateral peaks (Wasserman and Freeman, 1998). Cells within these two peaks of Egfr activity later differentiate a pair of dorsal appendages near the anterior of the egg (**Figure 2**), which are thought to mediate gas exchange for the enclosed embryo. Since *rho* expression requires the synergistic interaction of Egfr activity and a Dpp signal from the anterior follicle cells, the position of the dorsal appendages is thought to be regulated in part by limiting *rho* expression to an anterior-dorsal domain (Peri and Roth, 2000).

The function of *kek* is distinct from that of *argos*. Compared to *argos*, *kek* is induced in a broader domain and in a graded fashion, and *kek* is not required to define inter-dorsal appendage fate (Ghiglione *et al*., 1999). *kek* encodes a single-pass transmembrane protein that can directly interact with Egfr, so Kek may directly prevent ligand–receptor interactions (Ghiglione *et al*., 2003). Loss of *kek* is associated with a modest increase in Egfr activity, while ectopic *kek* expression suppresses Egfr activity, consistent with its role as an Egfr repressor. A much more pronounced dorsalized phenotype is caused by loss of *sprouty* (*sty*) (Reich *et al*., 1999). Like *kek*, *sty* expression is more broadly activated by Egfr and its overexpression can suppress Egfr

activity (Casci *et al.*, 1999; Reich *et al.*, 1999). Genetic evidence indicates that Sty acts cell-autonomously to impede Egfr signal transduction in the cytoplasm, although its mechanism of action is not well understood (reviews: in Leevers, 1999; Li *et al.*, 2003b).

A general inhibitor of Egfr activity in the follicle cells is the RING-finger E3 ubiquitin ligase Cbl. In mosaics, loss of *cbl* allows cell-autonomous ectopic Egfr activity, even in ventral follicle cells where *pipe* is repressed (Pai *et al.*, 2000). These effects depend on the presence of Grk, indicating that Cbl acts downstream of Egfr activation. Interesting connections exist between the human orthologs of Cbl, Sty, and Egfr: Cbl poly-ubiquitinates Egfr and hSpry2, and targets them to the proteasome for degradation (Wong *et al.*, 2002; Fong *et al.*, 2003; Hall *et al.*, 2003; Rubin *et al.*, 2003, and references therein). The Cbl-Egfr and Cbl-hSpry2 interactions require the phosphorylation of Egfr and hSpry2 to create Cbl-binding sites. Both phosphorylation events depend on Egfr activation, which induces its own degradation and that of Sty, while at the same time replenishing both proteins by increasing their transcription (Clark *et al.*, 1985; Reich *et al.*, 1999). In the presence of high levels of hSpry2, Egfr is not ubiquitinated or degraded, but instead remains on the cell surface in an activated state. Taken together, this information supports a model in which hSpry2 acts as an Egfr activator by sequestering Cbl, allowing sustained Egfr signaling activity.

However, this model cannot be easily assimilated with data in *Drosophila* and other organisms that implicate Sty in Egfr repression. A highly conserved carboxy-terminal cysteine-rich domain in hSpry2 mediates Egfr inhibition, while a highly conserved amino-terminal phosphotyrosine site bound by Cbl potentiates Egfr signaling (review: Li *et al.*, 2003b). Therefore, Sprouty proteins such as Sty and hSpry2 appear to have dual opposing functions in regulating Egfr activity, depending on their interaction with Cbl, which in turn is regulated by Egfr activity.

Different levels of Egfr activity delimit the domains of four types of follicle cells along the D–V axis of the egg: *argos*-expressing dorsal midline cells with low Egfr activity; adjacent domains with peaks of Egfr activity with *rho*, *kek*, and *sty* expression; lateral domains of decreasing Egfr activity which do not express *pipe* or Egfr-responsive genes; and ventral cells with little or no Egfr activity that express *pipe*. Different levels of Egfr activity appear to be induced by restricting Grk to the dorsal side of the oocyte, and fine-tuning and stabilizing Egfr activity through a complex set of regulatory feedback mechanisms that are only partly understood.

1.2.6.6.4. Embryonic dorsal/ventral polarity The expression of *pipe* is limited to the ventral follicle cells by dorsal Egfr activity in the ovary, and its localized activity establishes dorsal–ventral polarity in the embryo (**Figure 6**; reviews: Roth, 2003; Stathopoulos and Levine, 2002). *pipe* encodes a putative heparin sulfate 2-*O*-sulfotransferase that modifies extracellular matrix (ECM) proteins that localize to the perivitelline space of the egg (Sen *et al.*, 1998, 2000). Pipe-modified ECM proteins are thought to locally initiate a proteolytic cascade, involving Nudel (Ndl), Gastrulation defective (Gd), Snake (Snk), Easter (Ea), and the Serpin Spn27A, that locally activates Spätzle (Spz) in the ventral perivitelline space (review: LeMosy *et al.*, 1999). Spz activates the Toll (Tl) receptor, and the Tl signal is transduced by the Pelle (Pll) kinase, which leads to the phosphorylation and degradation of Cactus (Cact). Cactus normally binds to Dorsal and retains it in the cytoplasm, so Tl activity releases Dorsal and allows its nuclear import. Nuclear import of the Dorsal protein occurs in a ventral to dorsal gradient and is restricted to cells in the ventral 40% of the embryo. Dorsal is a member of the NF-κB family of transcription factors, and different thresholds in its nuclear concentration initiate the differentiation of the mesoderm, mesectoderm, and neurectoderm (review: Stathopoulos and Levine, 2002). At low concentrations, nuclear Dorsal restricts dorsal fate by repressing the expression of dorsal-specific genes such as *dpp*, while it activates the expression of *short gastrulation* (*sog*) and other genes necessary for neurectoderm fate (**Figure 6**). High concentrations of nuclear Dorsal specify mesoderm fate in ventral cells by activating expression of at least two target genes, *twist* (*twi*) and *snail* (*sna*), which then repress the expression of *sog* to restrict neurectoderm fate to two lateral domains.

1.2.7. Primordial Germ Cells

1.2.7.1. PGC Fate Specification

The germline is the first distinct cell lineage established in the *Drosophila* embryo when the pole cells, or PGCs, form at the posterior of the embryo during nuclear cycle 8 (**Figure 5**). PGCs are specified by a unique mechanism that involves cytoplasmic inheritance of RNAs and proteins that are localized to the posterior germ plasm during oogenesis.

The existence of morphologically distinct types of cytoplasm in the posterior region of the egg has been recognized for well over 100 years (review: Mahowald, 1992, 2001). The importance of germ plasm in PGC specification was first described in the beetles *Leptinotarsa* and *Calligrapha*, where experimental removal of the posterior oocyte cytoplasm resulted in larvae lacking germ cells (Hegner, 1908, 1911). In *Drosophila*, cytoplasmic transplantation of posterior pole plasm to the anterior of a recipient egg is sufficient to induce ectopic pole cells that are capable of forming germ cells when implanted to a host posterior (Illmensee and Mahowald, 1974). These important experiments firmly established the role of the germ plasm as the morphogenetic determinant of PGC fate.

Germ plasm contains specialized organelles called polar granules in *Drosophila* – electron-dense fibrous bodies of RNA and protein found only in the posterior oocyte (or early embryonic) cytoplasm or in germ cells (review: Mahowald, 2001). Polar granules are thought to store and regulate the translation of maternal mRNA required for embryonic germ cell determination (see below). Some of the maternal-effect mutations that block PGC formation, namely *capu*, *spir*, *osk*, *stau*, *valois* (*vls*), *tudor* (*tud*), and *vasa* (*vas*), result in the disappearance of polar granules, supporting the direct involvement of the respective gene products in PGC specification. Although in most cases the molecular mechanisms by which polar granule components regulate PGC fate remain obscure, some polar granule components appear to have direct roles in defining the PGC lineage.

Polar granule construction begins with the posterior localization of the first components of polar granules, *osk* mRNA and Stau, and is completed late in oogenesis with the addition of late-localizing mRNAs like *nos* (review: Mahowald, 2001). The critical role for *osk* in forming PGCs was demonstrated by experiments in which a chimeric mRNA containing the *osk* coding region fused to the *bcd* 3′UTR was ectopically localized to the oocyte anterior. A high level of localized *osk* activity was thus produced at the anterior pole, sufficient to direct the assembly of ectopic polar granules, and resulting in the formation of functional PGCs at the anterior (Ephrussi and Lehmann, 1992), reminiscent of those produced by transfer of posterior cytoplasm (Illmensee and Mahowald, 1974). Formation of *osk*-induced ectopic PGCs depends on the function of *vas* and *tud*, but not *capu*, *spir*, or *stau*. This indicates that *osk*, *vas*, and *tud* are centrally important for PGC formation, and that the other three genes function indirectly, perhaps through involvement in localizing Osk. Later work confirmed that Stau functions directly in the transport and posterior anchoring of *osk* mRNA. As discussed in Section 1.2.6.4, *capu* and *spir* encode Actin-binding proteins, and mutations in these genes affect several localization processes. Once produced, Osk is phosphorylated by the Par-1 kinase to stabilize it at the posterior (Bullock and Ish-Horowicz, 2002; Riechmann *et al*., 2002).

Vas is also a key component of polar granules. *vas* mRNA is abundant and uniformly distributed in the cytoplasm of the nurse cells and the oocyte, but Vas protein accumulates at the posterior pole of the oocyte beginning at early stage 10 (Hay *et al*., 1990; Lasko and Ashburner, 1990). Osk is required for posterior Vas accumulation, and Osk and Vas can directly interact, suggesting a direct function for Osk in anchoring Vas to the posterior (Breitwieser *et al*., 1996). Vas arrives a the posterior pole by a mechanism distinct from that of Osk, which is dependent on a second Vas-interacting protein, Gustavus (Gus) (Styhler *et al*., 2002). Vas is stabilized in the pole plasm through an association with the deubiquitination enzyme Fat facets (Faf), which also localizes to the posterior pole dependent on Osk (Fischer-Vize *et al*., 1992; Liu *et al*., 2003).

Vas is a DEAD-box RNA helicase related to the translation factor eIF4A. In *vas*-null mutants, Grk protein levels are reduced (Styhler *et al*., 1998; Tomancak *et al*., 1998). Because Vas can also interact with the general translation factor, dIF2/eIF5B (Carrera *et al*., 2000), it is a candidate translational activator of *grk* and, by extension, at least one of the polar granule mRNAs (review: Johnstone and Lasko, 2001). However, a direct role for Vas in regulating translation has not been absolutely established for any mRNA, nor have any specific Vas-binding RNA sequences or structures yet been identified. Prior to its localization at the posterior, Vas accumulates in punctate perinuclear RNP structures, referred to as the nuage (the French word for "cloud"), near the nurse cell nuclear pores. Other polar granule components, such as Tud and Aub, colocalize with Vas in the nuage (Harris and Macdonald, 2001). Prior to its own accumulation into polar granules, Aub is involved in RNA interference-mediated translational repression of unlocalized *osk* mRNA, potentially implicating the nuage in this process (Kennerdell *et al*., 2002; Findley *et al*., 2003). Thus, the nuage may well be the site where mRNAs are assembled with the proteins that control their localization and translation, a critical

step in the assembly of the transport and translational control machinery (Section 1.2.6.3).

Less is known about the third central gene implicated in germ cell specification, *tud*. PGCs do not form in *tud* mutants, even though some small polar granules have been observed in possibly hypomorphic alleles (Amikura *et al*., 2001). Tud contains 11 repeated copies of a domain of unknown function, termed the Tudor domain. Two related proteins in mouse, Mouse Tudor Repeat-1 (MTR-1), which is the probable Tudor ortholog, and the Survival of Motor Neuron (SMN) protein, have been implicated in direct protein–protein interactions with Sm proteins, the components of the small nuclear ribonucleoproteins (snRNPs) that are involved in RNA splicing (Selenko *et al*., 2001; Chuma *et al*., 2003, and references therein). The snRNPs are assembled in the cytoplasm, but are usually transported to and confined within the nucleus (Will and Luhrmann, 2001). In germline cells of other organisms, Sm proteins colocalize with *vasa* ortholog. This occurs in the perinuclear nuage of *Panorpa* nurse cells (Batalova and Parfenov, 2003), in *C. elegans* P-granules (Barbee *et al*., 2002), and with mouse *Mtr-1* in chromatoid bodies, large RNA and protein complexes that probably represent the mouse nuage (Chuma *et al*., 2003). The distribution of Sm proteins in *Drosophila* nurse cells and oocytes has not been reported. Accumulation of Sm proteins in the cytoplasm is unusual, and may reflect an association with translationally silent mRNAs during oogenesis.

In many species including *Drosophila*, the germ plasm is distinguished not just by the presence of polar granules, but also by a high concentration of mitochondria. Individual mitochondria are often closely juxtaposed with polar granules (Mahowald, 1992, 2001). Surprisingly, two mitochondrial ribosomal RNAs, *mtlrRNA* and *mtsrRNA*, are transported from the mitochondria and localized to the surface of polar granules (Kobayashi *et al*., 1993; Kashikawa *et al*., 1999). While these RNAs are not readily amenable to genetic studies, several lines of evidence support a function for them in germ cell specification. For example, irradiation of pole plasm with UV-light inactivates it (Geigy, 1931), and this inactivation is relieved by injection of *mtlrRNA* (Kobayashi and Okada, 1989). Furthermore, injection into the pole plasm of a ribozyme that specifically cleaves *mtlrRNA* significantly reduces subsequent PGC formation (Kobayashi *et al*., 1993; Iida and Kobayashi, 1998). Accumulation of *mtlrRNA* on the polar granules is greatly reduced in *tud* mutants, leading to the suggestion that Tud might mediate the transport of mitochondrial ribosomal RNAs to the polar granules (Amikura *et al*., 2001).

1.2.7.2. Cell Cycle Control and PGC Migration

The first 13 nuclear divisions in *Drosophila* embryos are synchronized and occur in a syncytium under maternal control. During syncytial nuclear divisions, nuclei form an ellipsoid array that expands from the interior of the embryo to its periphery (**Figure 5**), and during nuclear cycle 9, a few nuclei at the posterior pole contact the germ plasm, protrude and form pole buds. Pole buds divide twice during somatic cycles 9 and 10, and form complete cells at the end of cycle 10, well before somatic cellularization (see below). Polar granules are closely associated with dividing pole bud nuclei, and are specifically inherited by the PGCs upon cellularization. Some polar granule components, most notably Osk, disappear at this stage and are not inherited by the PGCs. Once formed, PGCs divide asynchronously, zero to two times, to form 30–35 large cells at the embryonic posterior. During the same interval, the somatic nuclei divide synchronously three more times (cycles 11–13). After the 13th division, extensions of the common cell membrane pull down between each of the somatic nuclei, and fuse basally to produce individual blastoderm cells (Wieschaus and Sweeton, 1988; Schüpbach and Wieschaus, 1989). At this time, the PGCs cease dividing, and remain quiescent throughout their migration and incorporation into the gonads. Germ cells outside the gonads or that migrate inappropriately are eliminated by apoptosis (review: Coffman, 2003).

As the germ band extends dorsally and anteriorly during gastrulation, the posterior midgut (PMG) invaginates and the PGCs are carried into the PMG lumen (**Figure 5**). They become amoeboid and migrate through the epithelium of the midgut, crawl dorsally over the basal surface of the midgut, then divide into two groups and move laterally to contact the somatic portion of the gonad in parasegments 10–12 (reviews: Starz-Gaiano and Lehmann, 2001; Muller, 2002). The somatic and germline cells coalesce to form the larval gonad. Each female embryonic gonad houses on average 12 PGCs that proliferate without differentiating during larval stages to produce a population of over 100 undifferentiated PGCs. They stop dividing, and some PGCs become germline stem cells at the larval-pupal transition after the development of the somatic GSC niche, while the remainder may directly differentiate as cystoblasts (Section 1.2.2).

In a large-scale screen of the third chromosome, Lehmann and colleagues have identified 25 zygotically required genes that affect germ cell

migration (Moore *et al.*, 1998), including *slow as molasses* (*slam*), *hedgehog* (*hh*), and *HMG-CoA reductase* (*hmgcr*). The novel protein Slam is proposed to guide PGCs off the midgut into the mesoderm (Stein *et al.*, 2002). *hh* is expressed in the somatic gonadal precursor cells, and is sufficient to attract PGCs to the gonad or to sites of ectopic *hh* expression (Deshpande *et al.*, 2001). One or more products of a lipid metabolism pathway involving Hmgcr, Farnesyl-diphosphate synthase, and Geranyl-geranyl-diphosphate synthase provide an attractive cue to PGCs, guiding them towards the gonadal mesoderm (Santos and Lehmann, 2004). Like *hh*, ectopic expression of *hmgcr* can alter the migration path of PGCs. These proteins are proposed to produce extracellular PGC guidance cues by protein geranylation, but the attractant itself has yet to be identified. The attractive signal operates antagonistically with the products of two other genes, *wunen* and *wunen2*. These phospholipid phosphatases repel PGCs from the ventral PMG to ensure dorsal migration (Zhang *et al.*, 1997; Van Doren *et al.*, 1998; Starz-Gaiano and Lehmann, 2001). These studies indicate that PGC migration is a multi-step process, controlled at individual stages by genetically separable mechanisms.

The receptor tyrosine kinase (RTK) encoded by *torso* (*tor*) is somatically expressed and is required for the activation of the Ras/MAP kinase signaling cascade and Stat in anterior and posterior embryonic cells (review: Duffy and Perrimon, 1994). Surprisingly, Ras and Stat are also activated in the PGCs, where they are required for the initial PGC mitotic divisions, and their migration (Li *et al.*, 2003a). Loss of maternal Stat or Ras causes a reduction in PGC numbers, while extra Stat activity dramatically increases their numbers, yet alterations in Stat or Ras activity does not affect the number of pole buds, strongly suggesting that they stimulate PGC divisions. Quiescent PGCs can be induced to divide by overexpression of String, an activator of Cdk1, or an activated form of Cdk1 that cannot be inhibited by phosphorylation, suggesting that inhibitory phosphorylation of Cdk1 induces cell cycle arrest in PGCs (Su *et al.*, 1998). How Stat and Ras cooperate to regulate the PGC cell cycle is not known. The Jak/Stat pathway has also been implicated in PGC migration (Li *et al.*, 2003a). It is interesting that Stat activation is also required for the migration of border follicle cells from the anterior of the egg chamber to the anterior of the oocyte (Beccari *et al.*, 2002; Ghiglione *et al.*, 2002), and like in PGCs, migration of border cells also depends on activated RTK signaling (Duchek *et al.*, 2001). There appears to be highly conserved associations between Stat activity and both increased cell proliferation and cell motility, but the molecular mechanisms are not clear (review: Hou *et al.*, 2002).

1.2.7.3. Transcriptional Repression in PGCs

During the later stages of oogenesis, polar granules mature with the addition of *nos*, *gcl*, and *pgc* RNAs. While *nos* is essential for posterior patterning, *gcl* and *pgc* have no known function besides germline development. In embryos produced by females mutant for any one of these genes, transcription in the PGCs, which is normally postponed until the PGCs approach the gonad, begins prematurely. Loss of transcriptional repression disrupts normal cell cycle control and PGC migration into the gonad.

Even prior to cellularization, the pole buds have greatly reduced levels of active RNA polymerase II that is phosphorylated on its C-terminal domain (CTD) (Leatherman *et al.*, 2002). However, the level of Pol II CTD phosphorylation is increased dramatically in most pole buds of *gcl* mutants (Leatherman *et al.*, 2002). Gcl is detectable at the posterior of early embryos, and it specifically associates with the nuclei that enter the germ plasm (Jongens *et al.*, 1992). Gcl is present at the nucleoplasmic face of the PGC nuclear envelopes, where it is detected until the PGCs migrate through the posterior midgut primordium. Its subcellular localization and phenotype suggest that Gcl may direct chromatin compaction (Jongens *et al.*, 1994), but its mechanism of action remains to be determined. While most *gcl* mutant embryos do not form PGCs, they do form pole buds, and some embryos form a few PGCs and develop into weakly fertile adults. The majority of *gcl* mutant pole bud nuclei misexpress somatic genes, such as *sisterless-a* and *scute*, and ectopic Gcl expression at the anterior of the embryo is sufficient to downregulate *sisterless-a* and *tailless* expression in anterior somatic cells (Leatherman *et al.*, 2002). The *gcl* phenotype suggests that transcriptional quiescence might be a prerequisite to PGC cellularization, while the few fully functional PGCs that form without *gcl* strongly suggest redundancy in the mechanisms that silence transcription in the germline. Transcriptional repression in PGCs is very robust since even the strong Gal4 : VP16 transcriptional activator is not sufficient to overcome it (Van Doren *et al.*, 1998).

Embryos produced from *nos* mutant females fail to establish or maintain transcriptional quiescence in their PGCs and fail to develop functional germ cells. Because *nos* is also required maternally for posterior patterning and thus embryonic viability,

its role in PGC development only became apparent through experiments whereby PGCs lacking *nos* were transplanted to a wild-type host (Kobayashi *et al*., 1996). PGCs mutant for *nos* abnormally transcribe a subset of somatic genes such as *Sex-lethal* (*Sxl*), and the segmentation genes *fushi-tarazu* and *even-skipped* (Kobayashi *et al*., 1996; Asaoka *et al*., 1998; Deshpande *et al*., 1999).

PGCs mutant for *nos* also fail to establish mitotic arrest and thus undergo extra divisions. Both the cell cycle and migration defects of *nos* mutant PGCs can be alleviated by the removal of the *Sxl* gene, indicating that *Sxl* must be silenced by Nos in order to properly specify PGCs. In the soma, Nos directly represses translation of maternal *hb* mRNA (review: Parisi and Lin, 2000), so its effect on transcription in PGCs is thought to be mediated indirectly through translational repression. Zygotic *hb* expression can be induced in ectopic PGCs by misexpressing *bcd* at the anterior, even in a wild-type *nos* background (Deshpande *et al*., 2004). Ectopic *bcd* expression can cause PGC migration and division defects, stimulate Pol II CTD phosphorylation, and induce *Sxl* expression, indicating that Nos-dependent translational repression is very important to transcriptional silencing in PGCs. Translational repression by Nos appears to be a highly conserved mechanism required for PGC development from worms to vertebrates (Subramaniam and Seydoux, 1999; Koprunner *et al*., 2001; Jaruzelska *et al*., 2003; Tsuda *et al*., 2003).

Polar granule component (*pgc*), which is believed to be a noncoding RNA, is also required to build functional PGCs through transcriptional silencing (Nakamura *et al*., 1996; Deshpande *et al*., 2004; Martinho *et al*., 2004). As for *gcl*, germ cells in embryos from females mutant for *pgc* have elevated levels of Polymerase II CTD phosphorylation, and express somatic genes such as *zerknüllt*, *tailless*, and *slam*. Loss of *pgc* also leads to increased levels of methylated Histone H3, which is associated with open chromatin state and suggests transcriptional activity. Again, these data suggest that transcriptional repression in PGCs might be established through regulating RNA Pol II function, but a direct role for *pgc* has not been defined. In contrast to *gcl*, *pgc* mutations do not affect the formation of germ cells, and unlike *nos*, *pgc* appears to have no role in somatic patterning (Martinho *et al*., 2004).

Not all somatic genes tested are misexpressed in *nos*, *gcl*, or *pgc* mutants, and a gene that is misexpressed in one mutant is not necessarily misexpressed in the others. Therefore, transcriptional repression may be accomplished in PGCs through partially redundant mechanisms. Although current evidence indicates the importance of transcriptional and translational repression in the PGC development, it is important to note that a single germ cell determinant has not yet been identified. Since the PGCs are undifferentiated until late in larval development, the germline may be specified by protecting PGCs from somatic patterning signals.

Acknowledgments

We would like to thank Jean-Paul Acco from the Department of Neurophotography at the Montreal Neurological Institute for his expert assistance in creating figures, and Lucia Caceres for critical comments on the manuscript.

Appendix: Gene Products and Functions in Oogenesis

Atypical protein kinase C (aPKC) Serine/threonine kinase. Asymmetric aPKC protein localization is involved in cell fate commitment and maintenance of epithelial apical–basal polarity and oocyte anterior–posterior polarity.

Apontic (Apt) RNA binding protein that, together with Bruno, is involved in negative regulation of *oskar* mRNA translation.

Argos (Aos) Secreted protein that directly inhibits Egfr activity in follicle cells along the dorsal midline, required to define interdorsal appendage fate.

Armadillo (Arm; β-Catenin) Adherens junction component required to maintain the germline and somatic stem cells in the stem cell niche.

***arrest* (*aret*)** See Bruno.

Aubergine (Aub) An eIF2C-related protein, originally identified by mutations that cause ventralized eggs, found in the perinuclear nuage and polar granules, involved in RNA interference-mediated translational repression.

Bag of marbles (Bam) Novel cytoplasmic protein that works together with Bgcn, mitotic cyclins, and their regulators drive cystocyte divisions only as long as Bam is present.

Barentsz (Btz) Nuclear shuttling protein, component of the exon-junction complex (EJC), required for posterior *osk* localization.

Bazooka (Baz) PDZ domain protein, *Drosophila* Par-3 ortholog, phosphorylated and negatively regulated by Par-1, binds aPKC.

Benign gonial cell neoplasm (Bgcn) An unusual RNA helicase-like protein, works together with Bam to promote cystocyte divisions.

Bicaudal-D (Bic-D) Required for oocyte differentiation, mutant egg chambers have 16 nurse cells

and no oocyte, involved in MT-dependent, Dynein-mediated transport of mRNA and protein from the nurse cells into the oocyte.

Bicoid (Bcd) Homeodomain-containing transcription factor defines cell fates along the anterior–posterior axis by activating *huchback* expression and repressing *caudal* translation in the embryo.

Big brain (Bib) Cell membrane protein, positive regulator of Notch signal reception, expressed in stalk cells.

Brainiac (Brn) Glycolipid-specific β1,3N-acetylglucosaminyltransferase, functions in the biosynthesis of glycolipids that might regulate extracellular signal-receptor interactions.

Bruno (Bru) RRM-containing RNA-binding protein encoded by *arrest (aret)*, binds to the Bruno response elements (BREs) of *osk* 3′UTR to repress translation of unlocalized *osk* in the ovary.

Cactus (Cact) Component of the Toll signaling cascade required for dorsal–ventral axis determination. Cact, an I-κB ortholog, inhibits nuclear translocation of Dorsal protein in ventral cells of the embryo by binding to and retaining Dorsal in the cytoplasm.

Cappuccino (Capu) Formin homology protein implicated in Actin cytoskeletal dynamics, required to repress ooplasmic streaming, maternal-effect mutations block PGC formation.

α-Catenin (α-Cat) Component of adherens junctions, has filamentous-Actin and Cadherin binding activity.

β-Catenin (β-Cat) See Armadillo (Arm).

Caudal (Cad) Homeodomain-containing transcription factor required for posterior patterning.

Cbl RING-finger E3 ubiquitin ligase, general inhibitor of Egfr activity in the follicle cells, polyubiquitinates Egfr and hSpry2 and targets them to the proteasome for degradation.

Cdc2/Cdk1 Cyclin-dependent kinase, regulates G2/M transition.

Cheerio Filamin, recruits Hts-RC and Actin to the ring canals.

Chickadee (Chic) *Drosophila* profilin, Actin-binding protein required to polymerize Actin filaments during nurse cell dumping.

Chk2 Serine/threonine protein kinase, transducer of the meiotic checkpoint that is activated by unrepaired double-strand DNA breaks.

Cop9 complex homolog subunit 5 (Csn5) Regulator of specific protein degradation, required in the oocyte for axis determination.

Cup Represses translation of unlocalized *osk* and *nos,* and is required for posterior localization of *osk* mRNA.

Cyclin A (CycA) Regulates G2/M transition, gain-of-function causes a significant fraction of cysts to form with 32 cells.

Cyclin B (CycB) Regulates G2/M transition, gain-of-function causes some cysts to form with 32 cells.

Cyclin E (CycE) G1 Cyclin , loss-of-function leads to cells with only eight cells.

DE-Cadherin Adherens junction component required to maintain the germline and somatic stem cells in the stem cell niche.

Decapentaplegic (Dpp) (TGF-β/BMP) extracellular ligand secreted by the somatic cells of the stem cell niche, represses the expression of *bag of marbles* and maintain GSC fate.

Delta (Dl) Extracellular membrane-bound cell surface ligand for the Notch receptor, required in the germline to activate Notch and specify polar cell fate.

Domeless (Dome) Cell-surface receptor in the Jak pathway.

Dorsal Member of the NF-κB family of transcription factors, regulated nuclear import and activity occurs in a ventral to dorsal gradient in ventral cells, and different thresholds in its nuclear concentration initiate the differentiation of the embryonic mesoderm, mesectoderm, and neurectoderm.

Dynactin Multiprotein complex including Dynamitin, Glued, and Lissencephaly-1, activates Dynein microtubule motor activity.

Dynamitin (Dnm) Component of the Dynein–Dynactin complex that activates Dynein microtubule motor activity.

Dynein Minus-end directed microtubule-dependent motor, its function is mediated by the multiprotein dynactin complex, made up of $p150^{Glued}$, p50 Dynamitin, and Lissencephaly-1.

Dynein heavy chain (Dhc) Protein component of the plus-end directed microtubule motor Dynein.

Easter (Ea) Serine endopeptidase, a component of the protease cascade that produces the Toll ligand during embryonic dorsal–ventral patterning.

Egalitarian (Egl) Required for oocyte differentiation, mutant egg chambers have 16 nurse cells and no oocyte, involved in MT-dependent, Dynein-mediated transport of mRNA and protein from the nurse cells into the oocyte.

Egghead (Egh) A Golgi-located β1,4-mannosyltransferase predicted to form the precursor glycolipid for Brn, functions in the biosynthesis of glycolipids that might regulate extracellular signal–receptor interactions.

Enhancer of split (E(spl)) Canonical Notch pathway target gene, encodes a helix–loop–helix-type transcription factor.

Encore (Enc) Novel protein, mutants produce 32-cell cysts with high frequency necessary for proper assembly of the SCF-complex (Skp/Cullin/Rbx1/F-box) on the fusome, which degrades CycE, negative regulator of Bam.

Epidermal growth factor receptor (Egfr) Important membrane-tethered extracellular receptor that is activated by TGF-α family ligands (e.g., Grk, Spi).

Eyes absent (Eya) A transcription cofactor whose expression must be repressed in the polar cells to allow their specification.

Even-skipped (Eve) Transcription factor, from the pair-rule class of segmentation genes.

Exuperantia (Exu) Protein is also a component of the *bcd* mRNP complex that is required for the anterior cortical localization of *bcd* Mrna.

Fasciclin III (FasIII) Cell adhesion molecule, expression marks undifferentiated follicle cells, and differentiated polar cells.

Farnesyl-diphosphate synthetase Enzyme proposed to modify the extracellular matrix to guide migrating germ cells during embryogenesis.

Fat facets (Faf) Deubiquitination enzyme that localizes to the posterior pole dependent on Osk, deubiquitinates and stabilizes Vas in the pole plasm.

Fringe (Fng) A glycosyltransferase that cell-autonomously modifies the Notch receptor to potentiate Dl to Notch signaling.

Fushi-tarazu (Ftz) Transcription factor, from the pair-rule class of segmentation genes.

Gastrulation defective (Gd) Serine endopeptidase, a component of the protease cascade that produces the Toll ligand during embryonic dorsal–ventral patterning.

Geranyl–geranyl diphosphate synthetase Enzyme proposed to modify the extracellular matrix to guide migrating germ cells during embryogenesis.

Germcell-less (Gcl) Late-localizing RNA, repress transcription in the embryonic germ cells, localizes to the nucleoplasmic face of PGC nuclear envelopes, might direct chromatin compaction.

Giant (Gt) Transcription factor, from the gap class of segmentation genes.

Glued (Gl) A component of the Dynein–Dynactin complex that activates Dynein microtubule motor activity.

Grapes (Grp) Inhibitory kinase of Cdc25-like proteins.

Gurken (Grk) Germline TGF-α-like secreted extracellular Egfr ligand.

Gustavus (Gus) VAS-interacting protein required for posterior localization of VAS.

Hedgehog (Hh) Extracellular ligand, expressed by the TF and cap cells, maintains somatic stem cell fate.

HMG-CoA reductase (Hmgcr) Component of a lipid metabolism pathway involving Farnesyl–diphosphate synthase, and Geranyl–geranyl–diphosphate synthase that provides an attractive cue to PGCs, guiding them toward the gonadal mesoderm.

hnRNPA1/Hrp40 See Squid.

Hopscotch (Hop) The *Drosophila* Janus kinase (Jak).

Hu-Li Tai Shao (Hts) Ring canal protein (Hts-RC) and fusome component.

Hunchback (Hb) Transcription factor, activates gap gene expression along the A/P axis of the embryo in a concentration-dependent manner.

K10 Can directly interact with Sqd, required for the movement of *grk* mRNA from the anterior cortex to the dorsal–anterior of the oocyte.

Kekkon (Kek) Single-pass transmembrane protein that repressed Egfr, can directly interact with Egfr, expected to prevent ligand–receptor interactions.

Kelch The final ring canal component to be added, required through oogenesis for the continued expansion of the ring canals.

Kinesin heavy chain (Khc) Component of conventional Kinesin, plus-end directed microtubule mediated motor complex.

Knirps (Kni) Transcription factor from the gap class of segmentation genes.

Laminin A (LanA) Structural component of the basal lamina extracellular matrix, required for substrate cell adhesion, cell migration, and survival.

Leonardo (14-3-3ζ) Protein kinase C inhibitor required for oocyte fate maintenance, and to establish oocyte cytoskeletal polarity.

Lissencephaly-1 (Lis-1) WD-repeat protein, interacts with the molecular motor cytoplasmic Dynein and its cofactor Dynactin, regulates Dynein function.

Mago Nashi (Mago) Nuclear shuttling protein, component of the exon-junction complex (EJC), required for posterior *osk* localization.

Mirror (Mirr) Homeodomain transcription factor, represses expression of the Notch signaling regulator *fringe*, and this is expected to localize Notch activity to the polar-stalk cell lineage.

Me31B DEAD-box RNA helicase that represses *osk* translation during transport from the nurse cells to the oocyte.

Medea (Med) Transcription factor required for the intracellular transduction of the Dpp (TGF-β) signal.

Meiotic-41 (Mei-41) Serine–threonine protein kinase, delays entry into mitosis in response to DNA damage.

Microtubule-associated protein/microtubule affinity-regulating kinase (MARK) Human Par-1 kinase ortholog.

Modulo (Mod) RRM-domain containing RNA-binding protein, required for *bcd* mRNA localization.

Moesin (Moe) Actin-binding protein, anchors microfilaments to the cell cortex, required to maintain epithelial cell polarity.

Mothers against Dpp (Mad) Component of the Dpp (TGF-β) intracellular signaling cascade, nuclear translocation is essential for Medea function.

mtlrRNA and mtsrRNA Two mitochondrial ribosomal RNAs that localize to polar granules and function in germ cell specification.

Nanos (Nos) Interacts with Pumilio to repress translation of *hb* and presumably other RNAs required to repress transcription in PGCs.

Neuralized (Neur) RING-finger DNA-binding protein and ubiquitin ligase that promotes degradation of Delta. Notch target gene, specifically expressed in polar cells.

No distributive disjunction (Nod) Kinesin-family motor, required for meiotic chromosome segregation.

Notch (N) Important membrane-bound extracellular receptor protein.

Nudel (Ndl) Extracellular serine protease in the Toll dorsal–ventral signaling pathway, locally activates the serine protease cascade that produces the Toll ligand.

Oo18 RNA-binding protein (Orb) *Drosophila* ortholog of Cytoplasmic polyadenylation element-binding protein (CPEB), believed to stimulate translation of specific mRNAs that contain a CPE sequence by mediating an extension of their poly(A) tails.

Okra DEAH-type DNA helicase with an SNF2 domain, ortholog of RAD52 in other organisms.

Orbit/Mast Microtubule-binding protein, required for spindle assembly during mitosis, stem cell and cystocyte divisions and oocyte differentiation.

Oskar (Osk) Protein sufficient to direct the assembly of ectopic polar granules, polar granule component, maternal-effect mutations block PGC formation.

Par-1 Serine–threonine kinase, phosphorylates Osk and anchors it at the posterior. Acts in a conserved pathway that regulates cell polarity and MT dynamics, may function similarly to its mammalian orthologs, the microtubule-affinity regulating kinases (MARKs), which phosphorylate microtubule-associated proteins (MAPs) to destabilize MTs.

Par-3 See Bazooka.

Par-5 (14-3-3ϵ) Protein Kinase C inhibitor, required for oocyte fate maintenance, and to establish oocyte cytoskeletal polarity.

Par-6 Required to establish epithelial and oocyte polarity, Baz and Par-6 proteins are interdependent for their asymmetric localization at the apical cell cortex of epithelial cells and neuroblasts in the embryo.

Patched (Ptc) Transmembrane receptor for Hedgehog.

PDZ domain Approximately 90 residue protein-recognition domain.

Pelle (Pll) Serine/threonine protein kinase required for transduction of the Toll signal in dorsoventral embryonic patterning.

Pipe Putative heparin sulfate 2-O-sulfotransferase that modifies extracellular matrix (ECM) proteins modified ECM proteins are expected to locally initiate a proteolytic cascade is both necessary and sufficient to induce embryonic ventral fates.

Piwi Autonomously required in the TF cells and cap cells for stem cell survival, founding member of a conserved class of proteins (the Piwi, Argonaute, or PPD family) that function in stem cell maintenance. Involved in RNA interference pathway.

***polar granule component* (*pgc*)** Late-localizing nontranslated RNA that is required for transcriptional repression in the PGCs.

Poly-A binding protein (Pabp) RRM-domain RNA-binding protein, binds to the 3′poly-A tail of mRNA, positive regulator of mRNA stability and translation.

Profilin See Chickadee.

Pumilio (Pum) RNA-binding protein, complexes with Nanos, required in the germline for the maintenance of GSCs, mutants fail to establish or maintain transcriptional quiescence in their PGCs.

Punt (Put) Type II transmembrane Dpp (TGF-β) receptor.

Quail Villin-related protein thought to cross-link Actin filaments to form bundles.

Ras GtPase, key intermediate in G-protein coupled receptor signaling pathways.

Raf Serine/threonine protein kinase, key intermediate in receptor tyrosine kinase-mediated intercellular signaling pathways.

Rhomboid (Rho) Protease that cleaves Spitz in the Golgi, allowing its secretion.

SCF-complex Multiprotein complex of SKP1, Cul1, and an F-box protein that catalyzes the polyubiquitination of proteins, a modification required for their degradation by the 26S proteasome.

Scute (Sc) Transcription factor, first expressed in early embryogenesis in cells with neurogenic potential.
Sex-lethal (Sxl) RNA-binding protein, expressed in females but not males, controls sex-specific alternative splicing and translation required for sex determination.
Short gastrulation (Sog) Secreted BMP-binding protein that narrows the domain of dorsal Dpp (TGF-β/BMP) activity during dorsal–ventral axis patterning in the embryo.
Short stop (Shot) Large cytoskeletal linker protein called spectraplakin, fusome component that binds and stabilizes microtubules.
Shutdown (Shu) Similar to the heat-shock protein-binding immunophilins, required for the production of 16-cell cysts during oogenesis.
Serpin47A Serine protease inhibitor, mutants show uniform high levels of Toll signaling.
Singed (Sn) Fascin-related protein expected to cross-link Actin filaments to form bundles.
Sisterless-a (SisA) Transcription factor required for endoderm migration, midgut formation, and sex determination.
Slow as molasses (Slam) Novel protein required for cellularization and proposed to guide PGCs off the midgut into the mesoderm.
Smaug (Smg) RNA-binding protein, binds to the 90-nucleotide translational control element (TCE) in the *nos* 3′UTR and represses *nos* translation by blocking eIF4G recruitment.
Smooth (Sm) RNA-binding protein, component of *bicoid* mRNA–protein complex.
Snail (Sna) Transcription factor, required for ventral furrow formation at gastrulation.
Snake (Snk) Serine endopeptidase, a component of the protease cascade that produces the Toll ligand during embryonic dorsal–ventral patterning.
Soft-boiled female sterile mutation causing the production of cysts with 16 nurse cells and no oocyte.
Spätzle (Spz) extracellular ligand for the Toll receptor, Easter cleaves and activates SPZ on the ventral side of the embryo.
α-Spectrin (α-Spec) Membrane skeletal protein, structural component of the fusome, which is required for ovarian cyst formation.
Spindle (Spn) A group of proteins involved in DSB repair, mutations cause decreased Grk accumulation and fragmented chromosomes in the oocyte nucleus.
Spire (Spir) Putative G-Actin-binding protein implicated in Actin cytoskeletal dynamics, required to repress ooplasmic streaming, maternal-effect mutations block PGC formation.
Spitz (Spi) A secreted Egfr ligand.
Sprouty (Sty) Negative regulator of EGF signaling
Squid (Sqd) RRM-domain containing heterogenous nuclear RNA-binding protein (hnRNPA1 or Hrp40) that binds *grk* RNA.
Stat (*Stat92E)* Intracellular mediator of Jak signaling, transcription regulator.
Staufen (Stau) Double-stranded RNA-binding protein, required for posterior *osk* mRNA localization and a late *bcd* mRNA localizaton step, polar granule component, maternal-effect mutations block PGC formation.
Stonewall (Stwl) Transcription factor required for oocyte fate determination.
String (Stg) Drosophila Cdc25 kinase homolog, derepress the Cyclin-dependent kinase Cdk1 to initiate the G2/M transition, overexpression causes cysts to form with only eight cells.
Swallow (Swa) RRM-domain and coiled-coil domain containing protein that interacts with Dynein light chain (Dlc), possible adaptor between the Dynein motor complex and *bcd* mRNA, required for the anterior localization and anchoring of *bcd*.
Tailless (Tll) transcription factor required to determine embryonic posterior and anterior terminal regions.
Ter94 an AAA-ATPase, a fusome component also associated with the endoplasmic reticulum.
Toll (Tl) transmembrane receptor required to define positional information along the dorsal–ventral embryonic axis.
Torso (Tor) somatically expressed receptor tyrosine kinase (RTK) that activates the Ras/MAP kinase signaling cascade and Stat in anterior and posterior embryonic cells and PGCs, required for the initial PGC mitotic divisions, and PGC migration.
Tribbles (Trbl) cell cycle regulator, inhibits STG in embryonic and cystocyte cell cycles by inducing its degradation, misexpression causes the formation of 32 cell cysts.
Tropomyosin II (TmII) Actin-binding protein required to anchor *oskar* mRNA to the posterior cortex of the oocyte.
Tsunagi (Tsu) nuclear shuttling hnRNP RNA binding protein, ortholog of vertebrate Y14, component of the exon junction complex (EJC), required for posterior *osk* mRNA localization.
γ-Tubulin Ring Complex (γTuRC) Associates with centrosomes and the egg cortex, mediates nucleation of microtubule minus ends.
Tudor (Tud) Centrally important for PGC formation, Tud contains 11 repeated copies of the Tudor domain, thought to mediate protein–protein interactions, maternal-effect mutations block PGC formation.

Twine (Twe) CDC25 protein tyrosine phosphatase, essential for meiotic G2/MI transition during oogenesis and has a role in regulating mitosis in the syncytial embryo.
Twist (Twi) Transcription factor required to specify mesodermal muscle fate, target of the Toll signaling pathway.
UbcD1 E2 ubiquitin-conjugating enzyme.
Unpaired (Upd) Extracellular Jak ligand, expressed in the polar cells.
Valois (Vls) Maternal-effect mutations affect posterior patterning and block PGC formation.
Vasa (Vas) DEAD-box RNA helicase related to the translation factor eIF4A, polar granule component, centrally important for PGC formation, probable translational activator of *grk* in early oocytes.
Wingless (Wg) Extracellular WNT-family ligand, expressed by the TF and cap cells, maintains somatic stem cell fate.
Wunen and Wunen2 Phospholipid phosphatases required to repel PGCs from the ventral PMG to ensure dorsal migration.
Yb P-loop containing nucleoside triphosphate hydrolase, autonomously required in the TF cells and cap cells for stem cell survival, positive regulator of both *hh* and *piwi* expression.

1.3.1. Introduction

Female insects typically produce prodigious numbers of eggs to assure the propagation of their genes, and invest considerable resources towards this end. Ultimately, the egg of an insect must contain a haploid set of chromosomes, sufficient nutrients to supply the growing embryo with resources to last until the larva or nymph ecloses and begins feeding, and a set of determinants to direct the organization and progression of embryogenesis, including the differentiation of a new cluster of germ cells. As with all organs, the morphology of the ovary reflects the physical and genetic requirements of its physiological role, which in this case is the functional assembly of the various components of the oocyte.

Visual inspection shows that the polytrophic ovary of holometabolus insects, which represent a major focus of this chapter, is comprised of a series of ovarioles that contain linear arrays of progressively developing follicles starting with dividing germ stem cells at one end and ending with mature oocytes ready for fertilization at the other (Figure 1). Essentially, the ovariole can be considered an assembly line leading to the production of the egg. How this assembly line operates within different species to produce similar end products, i.e., the mature oocytes, depends on the insect, its life style, and its evolutionary history.

1.3.2. Previtellogenesis: The Development of the Ovarian Structure

In this section, the development of the ovary and oocyte in the fruit fly, *Drosophila melanogaster*, is examined briefly and then extend the discussion to other insects, mainly Lepidoptera and non-*Drosophila* Diptera, where most of the additional relevant information is available.

1.3.2.1. *Drosophila melanogaster*

The organogenesis of the ovary and the production of eggs in *Drosophila* is one of the most completely examined developmental systems. From the formation of germ cells in the embryo to the localization

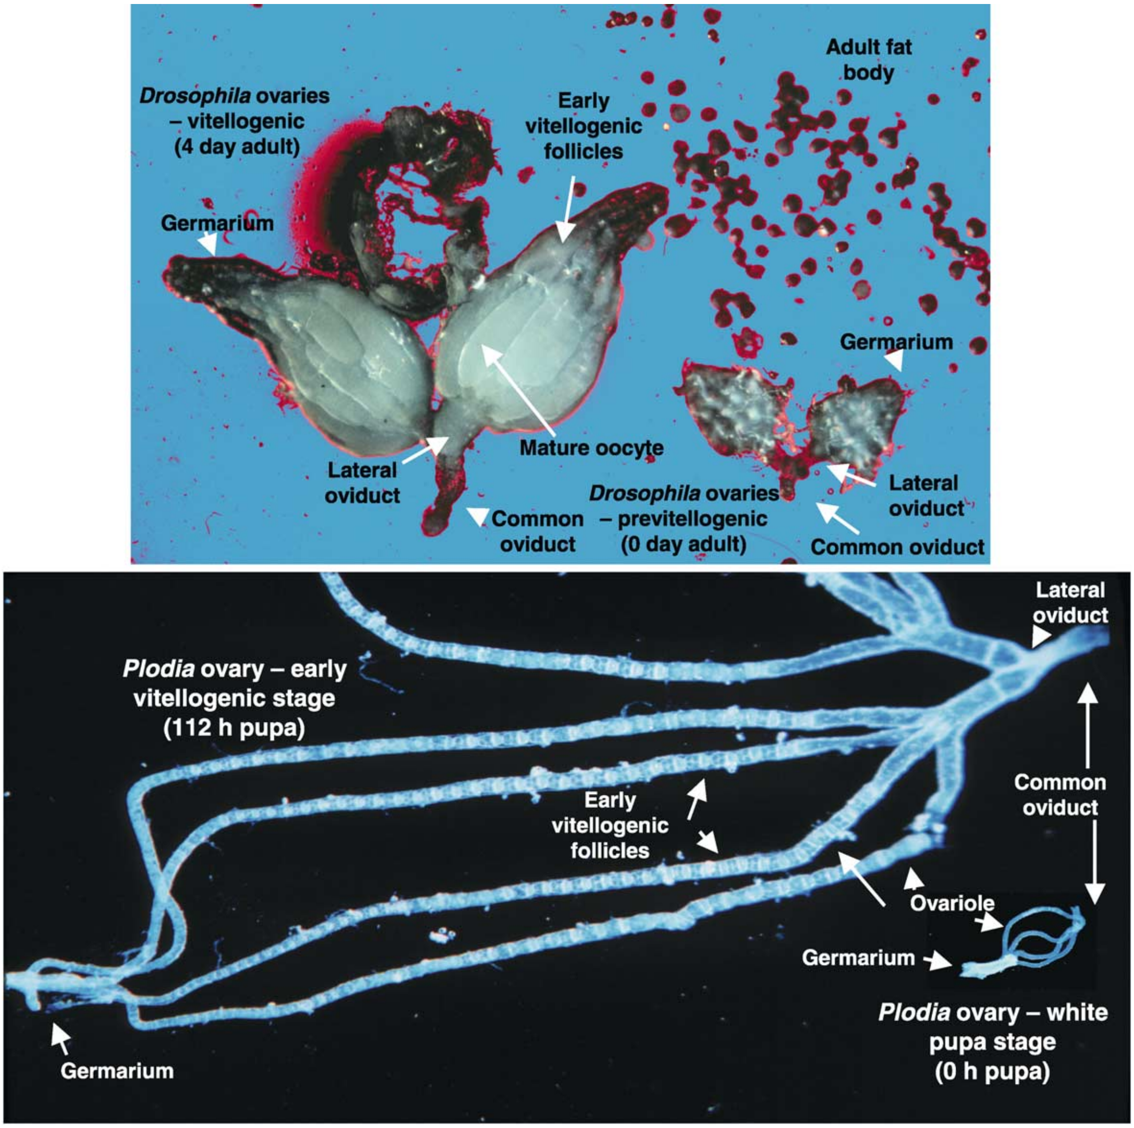

Figure 1 Ovaries of holometaboulous insects. The upper panel shows ovaries dissected from previtellogenic (newly eclosed) and vitellogenic (four day old) *Drosophila melanogaster* adult females. The increase in size of the ovaries is due to the uptake of yolk proteins and other nutrients by the maturing follicles. The lower panel shows ovaries dissected from early vitellogenic (112 h) and prefollicular (white or 0 h) *Plodia interpunctella* female pupae. The increase in size is due to the growth of the germ and somatic tissues of the ovary. The linear array of developing follicles can be seen within each ovariole extending from the germarium to the lateral oviduct. The size of the ovary will increase again as the follicles complete vitellogenesis.

of germ cell determinants in the oocytes within the ovary of the adult female, the growth and activities of the ovary and follicles have been examined extensively to determine the fundamental genetic and developmental processes that are involved in the production of an egg. As a result, the structural organization of the ovary and the developmental processes controlling its formation have been studied in-depth for over three-quarters of a century (Dobzhansky, 1930; Kerkis, 1930; Demerec, 1950; King *et al.*, 1968; King, 1970; Mahowald and Kambysellis, 1980; Spradling, 1993; Lasko, 1994; Mahajan-Niklos and Cooley, 1994; Dobens and Raftery, 2000; Houston and King, 2000) (see **Chapter 1.2**).

In *Drosophila*, the female molts into the adult stage with an immature ovary but, under the influence of juvenile hormone (JH), it initiates yolk protein production (vitellogenesis) and follicle maturation within the first day of adulthood (reviews: Postlethwait and Shirk, 1981; Bownes, 1986; Lasko, 1994). The female continues producing eggs throughout its life, provided a sufficient supply of nutrients is available (Bownes, 1986). Because the process of egg production is continuous, plentiful experimental material is always at hand, providing

a rich resource for the manipulation and analysis of oocyte production and maturation.

Under the influence of determinants localized within the posterior pole plasm of the embryo, the germ cells are the first to cellularize in the syncytial embryos (reviews: Spradling, 1993; Houston and King, 2000) (see **Chapter 1.2**). The formation of the pole plasm within the oocyte is dependent upon the maternal contribution and posterior localization of transcripts for *oskar* (*osk*; Lehman and Nüsslein-Volhard, 1986), *nanos* (*nos*; Nüsslein-Volhard *et al*., 1987), and *germ cell-less* (*gcl*; Jongens *et al*., 1992, 1994), as well as the proteins Staufen (Stau; Schüpbach and Wieschaus, 1986), Valois (Vls; Schüpbach and Wieschaus, 1986), Vasa (Vas; Schüpbach and Wieschaus, 1986), Tudor (Tud; Boswell and Mahowald, 1985; Schüpbach and Wieschaus, 1986), and Mago-nashi (Mago; Boswell *et al*., 1991). In addition to these determinants, normal germ cell development and dorsoventral patterning are also dependent on the posterior localization of Cappuccino (Capu) and Spire (Spir) (Manseau and Schüpbach, 1989) through the organization of microtubules and regulation of cytoplasmic streaming. Furthermore, germ cell development and posterior somatic patterning require posterior localization of the *nos* and *pumilio* (*pum*) transcripts (Lehman and Nüsslein-Volhard, 1987). These transcripts and proteins are produced in the nurse cells and sequentially localized in the posterior of the embryo. The transcripts include a 630-nucleotide sequence within the 3′ untranslated region, which specifies the localization signal that interacts with microtubules to facilitate translocation (Macdonald and Struhl, 1988; Pokrywka and Stephenson, 1991, 1995; review: **Chapter 1.2**). Once associated with the microtubules, the translocation of these determinants from the nurse cells to the oocyte and their stable localization within the embryo is dependent on activities of the microtubules, which function both via minus- and plus-end-directed motors driven by dynein and kinesin, respectively (reviews: Pokrywka, 1995; Stebbings *et al*., 1995) (see **Chapter 1.2**).

The number of germ cells formed in the embryo is influenced by the levels of Osk (Smith *et al*., 1992). A threshold level of Osk is required for normal germ cell formation and establishment of normal body patterning, while its over-expression leads to ectopic formation of pole cells as well as formation of additional posterior pole cells (for additional details, see **Chapter 1.2**). After cellularization of the germ cells, their migration and eventual localization within the gonads can be visualized using antibody staining for the Vas protein (Lasko and Ashburner, 1990), an RNA helicase that is constitutively expressed in germ cells (Hay *et al*., 1988; Lasko and Ashburner, 1988). Nearly half of the originally formed pole cells are lost during embryogenesis, as they migrate from the posterior of the germ band to their position within the embryonic gonads, and only 10–15 germ cells are present within the late embryonic gonad (Lasko and Ashburner, 1990; Mueller, 2002) (see **Chapter 1.2**).

Throughout most of the larval stages, the germ cells divide mitotically to produce an unorganized mass of primordial germ cells mixed with somatic cells (Kerkis, 1930). Midway through the third instar, however, the metamorphosis of the ovary is initiated, leading to the organization of the somatic and germ cells into the adult organ (King *et al*., 1968) (see **Chapter 1.2**). The morphogenetic changes in the undifferentiated ovary begin approximately 12 h after the molt to the third (last) instar, when the anterior somatic cells of the ovary express Ultraspiracle (USP; Oro *et al*., 1990) and the A isoform of the ecdysteroid (or ecdysone) receptor (EcR-A; Hodin and Riddiford, 1998). In the presence of low levels of ecdysteroids, these two proteins interact to activate downstream gene expression including that of the *bric à brac* (*bab*) gene. Under the influence of the BAB protein, approximately 20 terminal filament stacks begin to differentiate from the somatic cells (Godt and Laski, 1995; Sahut-Barnola *et al*., 1995).

After initiating differentiation, the terminal filament cells maintain high levels of USP but no detectable EcR (Hodin and Riddiford, 1998). The first two terminal filament stacks form on the medial side of the ovary, with new stacks forming more laterally, as progressively more are added until 32 h after the molt (Godt and Laski, 1995). By the time of pupariation, the 13–20 terminal filaments, which consist of stacks of 8–9 disk-shaped cells, have been formed in the ovary. These terminal filament stacks establish the positions for the formation of each of the ovarioles within the ovary.

Within 48 h from pupariation, the morphogenesis of the ovary is completed. A small cluster of cells forms at the base of the terminal filaments, in direct contact with the 2–3 germ cells localized within each ovariole (Lin, 2002) (see **Chapter 1.2**). The somatic cap cells and inner sheath cells surround the germ cells and form a niche that provides the signaling that controls germ cell divisions during the adult reproductive period (see **Chapter 1.2**). The primary germ cells function as stem cells and divide asymmetrically to produce one daughter cell that becomes a cystoblast, which enters follicle differentiation, and another daughter cell that retains a stem cell function (reviews: Spradling *et al*., 2001;

Lin, 2002) (see **Chapter 1.2**). The cap cells, alternatively, express several genes, e.g., *hedgehog* (*hh*), *piwi*, *fs(1)Yb*, and *decapentapalegic* (*dpp*), whose function is required for the maintenance of stem cell function (Cox *et al*., 1998; Xie and Spradling, 1998; King and Lin, 1999; Cox *et al*., 2000; Xie and Spradling, 2000; King *et al*., 2001) (see **Chapter 1.2**). Of these genes, *dpp* is the major regulator for clonal expansion of germ cells during the formation of the niche at the early pupal stage (Zhu and Xie, 2003).

The establishment of the stem cells within the niche requires fewer germ cells than are present at pupation, and stem cells that are not included in the niche differentiate directly into cystoblasts (Bhat and Schedl, 1997). Establishment of the germ stem cells is also dependent on the formation of *adherens* junctions between the cap cells and germ stem cells (Song *et al*., 2002). In addition to establishing their identity, they also provide a further physical constraint leading to asymmetric division of the germ stem cells, which is important for the renewal of the stem cells (Zhu and Xie, 2003).

Each ovariole in a mature ovary is divided into three regions, the terminal filament, the germarium, and the vitellarium (**Figures 1** and **2**). Within the germarium, four functional regions, 1, 2A, 2B, and 3, have been described (Koch and King, 1966; Mahowald and Strassheim, 1970; Lasko, 1994) (see **Chapter 1.2**), where the previtellogenic follicle forms (**Figure 2**). A cluster of 2–3 germ stem cells is found within a niche in the anterior-most section of the germarium (region 1), immediately adjacent to the terminal filaments (Wieschaus and Szabad, 1979). During egg production by the adult female, germ stem cells divide asymmetrically to produce cystoblasts and new stem cells (review: Lin, 2002; **Chapter 1.2**). The asymmetry of the cell division is necessary for maintenance of the stem cells, so that eggs can be produced throughout the adult stage.

In addition to anchoring the germ stem cells to the cap cells, polarized division of the daughter cells is maintained by the asymmetric segregation of the fusome (or spectrosome) in the germ stem cell. The fusome is a ring-shaped organelle replete with membrane skeletal proteins including actin (Warn *et al*., 1985; Theurkauf *et al*., 1992), α- and β-spectrins (de Cuevas *et al*., 1996), filamin and ankyrin (Li *et al*., 1999), motor molecules such as cytoplasmic dynein (McGrail and Hays, 1997), and the unique fusome proteins Hu-Li Tai Shao (HTS, an adducin-like protein; Yue and Spradling, 1992; Ding *et al*., 1993), Bag-of-marbles (BAM; McKearin and Ohlstein, 1995), TER94 (León and McKearin, 1999), and Kelch (Xue and Cooley, 1993). The fusome acts in

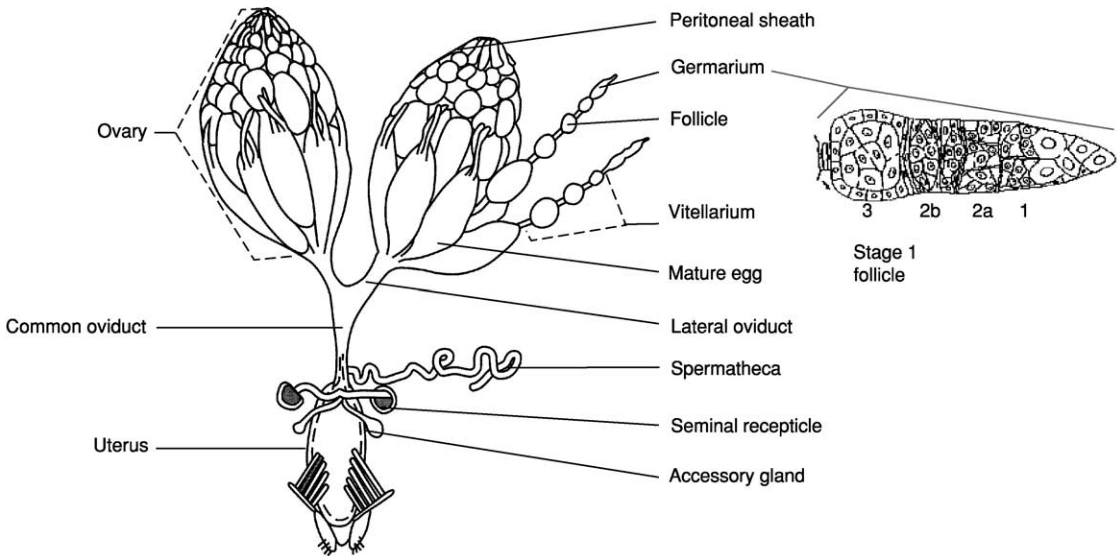

Figure 2 The reproductive system of *Drosophila melanogaster* contains two ovariole clusters that connect to a common oviduct. Eggs pass through the oviduct and are momentarily stored in the uterus until egg deposition. The broken line indicates the position of the mature egg in the uterus (the posterior end faces down). (Redrawn from Miller, A., **1950**. The internal anatomy and histology of the imago of *Drosophila melanogaster*. In: M. Demerec, M. (Ed.), Biology of *Drosophila*. Wiley, New York, pp. 420–534). The germarium contains germline stem cells (region 1) and mitotically active 2-, 4-, and 8-cell clusters. Clusters of 16 germline cells are present in 2a, where follicle cells begin to migrate around the cluster. Young egg chambers completely surrounded by follicle cells flatten into a lens shape in region 2b. The egg chamber reaches region 3 of the germarium (stage 1), where it becomes spherical and prepares for departure from the germarium as a stage 2 egg chamber. (Redrawn in part from Robinson, D.N., Cant, K., Cooley, L., **1994**. Morphogenesis of *Drosophila* ovarian ring canals. *Devel. 120*, 2015–2025).

determining the asymmetrical division of the dividing germ stem cells by associating with the cap cell-anchored germ stem cell pole of the mitotic spindle in subsequent mitoses of the cystocytes (Storto and King, 1989; Lin and Spradling, 1995; McGrail and Hays, 1997; Máthé *et al.*, 2003) (see **Chapter 1.2**).

The polarization of fusome localization is accomplished under the influence of *pum* whose product is involved in the organization of the microtubule structure (Lin and Spradling, 1997), and the Orbit/Mast and CLIP-190 proteins, which mediate interactions between microtubules and cytoskeletal organelles (Máthé *et al.*, 2003). The Orbit/Mast protein is found initially at the poles of the mitotic spindle but subsequently moves, coincident with the arrested cleavage furrow. This guides the migration of the fusome plugs toward the site of the pre-existing fusome (Storto and King, 1989), and assures the polarized positioning of the fusome and the asymmetry of germ stem cell division.

Following its separation from the germ stem cell, a cystoblast divides four times, with incomplete cytokinesis, within region 2A. This produces the cystocyte complex. The complex is composed of the oocyte that is connected by cytoplasmic bridges to the 15 nurse cells. The asymmetric division of the cystocytes leads to the assignment of one cell as the oocyte, with the remaining daughters of the cystocyte progeny becoming nurse cells (Storto and King, 1989; Lin and Spradling, 1995; McGrail and Hays, 1997; Máthé *et al.*, 2003; review: **Chapter 1.2**). After the formation of the oocyte–nurse cell complex, the dividing mesodermal cells, associated with the *tunica propria* in region 2B, separate from this membrane and attach to the oocyte–nurse cell complex as follicle cells (also known as follicular epithelium cells; this term is used predominantly in this chapter). These eventually intercalate between the germ cells (Margolis and Spradling, 1995). The formation of the differentiated previtellogenic follicle (oocyte–nurse cell complex surrounded by the follicular epithelium cell monolayer) is completed within region 3, and the assembled follicle is expelled into the vitellarium. There it undergoes the transition from previtellogenesis to vitellogenesis and, subsequently, the transition to choriogenesis and ovulation.

During vitellogenesis, the oocyte receives material from the nurse and follicle cells and from the hemolymph. Some of these components represent differentially distributed determinants that establish pattern formation during early embryonic development, while others are nutrients necessary for the completion of embryogenesis. Upon completion of provisioning the oocyte and before the follicle is expelled into the oviduct, the follicle undergoes the transition into the choriogenic period. During this period, the oocyte is first sealed within a vitelline membrane before being covered by the chorion (see Section 1.3.3.8 below).

1.3.2.2. Lepidoptera

Many lepidopteran species have a relatively short, nonfeeding adult stage, which requires the adult female to emerge with most of her eggs ready to be fertilized and oviposited within hours. This life style constrains these insects to a program of ovarian organogenesis and follicle development that must occur at stages earlier than in *Drosophila*. Although the information base for ovarian and follicular cell development in the Lepidoptera is limited, this section will summarize the information that is available, and compare it with that obtained from *Drosophila*.

In the embryos of the domesticated silkworm, *Bombyx mori*, the primordial germ cells form a single cluster in the lateral and ventral region, which is associated with the localization of the *vasa* transcript (Nakao, 1999) rather than posteriorly, as in *Drosophila* (Hay *et al.*, 1990; Lasko and Ashburner, 1990). The lateral location of the primordial germ cell cluster was suggested previously from electron microscopy observations (Miya, 1958, 1959) but, due to the absence of specific molecular markers, its position could not been confirmed. Nevertheless, the existing information suggests that the determinants required for germ cell formation are similar in moths and *Drosophila*, but there are spatial differences in their localization within the presumptive germ band.

The germ cells of *Manduca sexta* are first detected after germ band formation with a monoclonal antibody, 3B11, that specifically immunostains the large primordial germ cells (Nardi, 1993). These are observed as a loose aggregate in the midline of the embryo near the posterior pole, as is the case with *B. mori*, rather than directly posterior as in *Drosophila*. After segmentation of the embryo, the germ cells are distributed between three abdominal segments, and segregate laterally into two groups. Subsequently, the primordial germ cells form two tight clusters of 18–30 cells each that are localized within the fifth abdominal segment.

Ovary development in the Indian meal moth, *Plodia interpunctella*, was examined during the larval, pupal, and adult stages using an immunostain for the α-crystallin 25 kDa protein (αcp25), which is found primarily in the germ cells (Zimowska *et al.*, 1991; Shirk and Zimowska, 1997; Shirk *et al.*, 1998). In the newly hatched first instar *Plodia* larva, each gonad contains a single cluster of 28 germ cells (Beckemeyer and Shirk, in press). The

gonads retain this morphology until the end of the first instar, when the germ cells of each ovary are segregated into four clusters of seven germ cells each (Figure 3, upper left; Beckemeyer and Shirk, in press). This segregation of the germ cells is completed in the early second instar, when the morphology of the four ovarioles within each gonad can be discerned (Figure 3, upper right; Beckemeyer and Shirk, in press). The organization of the ovarioles within the *Plodia* ovaries occurs much earlier than in *Drosophila*, where it begins at the end of the last larval instar. Whether the organization of the terminal filaments in *Plodia* is dictated by the localized expression of a *bab*-like gene within the undifferentiated somatic cells, as is the case with *Drosophila* (Godt and Laski, 1995), has yet to be determined.

No divisions of the primordial germ cells are observed until after the formation of the ovarioles is complete in the late second instar. Soon after the molt to the third instar, however, germ cell divisions begin, but there appears to be a separation between the seven founding primordial germ cells, which are maintained in the apical region of the ovarioles (Figure 3, lower left). The segregation of these seven cells may represent physically the niche of the germ stem cells in this moth. By the end of the penultimate instar, each ovariole contains about 56 germ cells. The cluster of seven germ cells is maintained at the

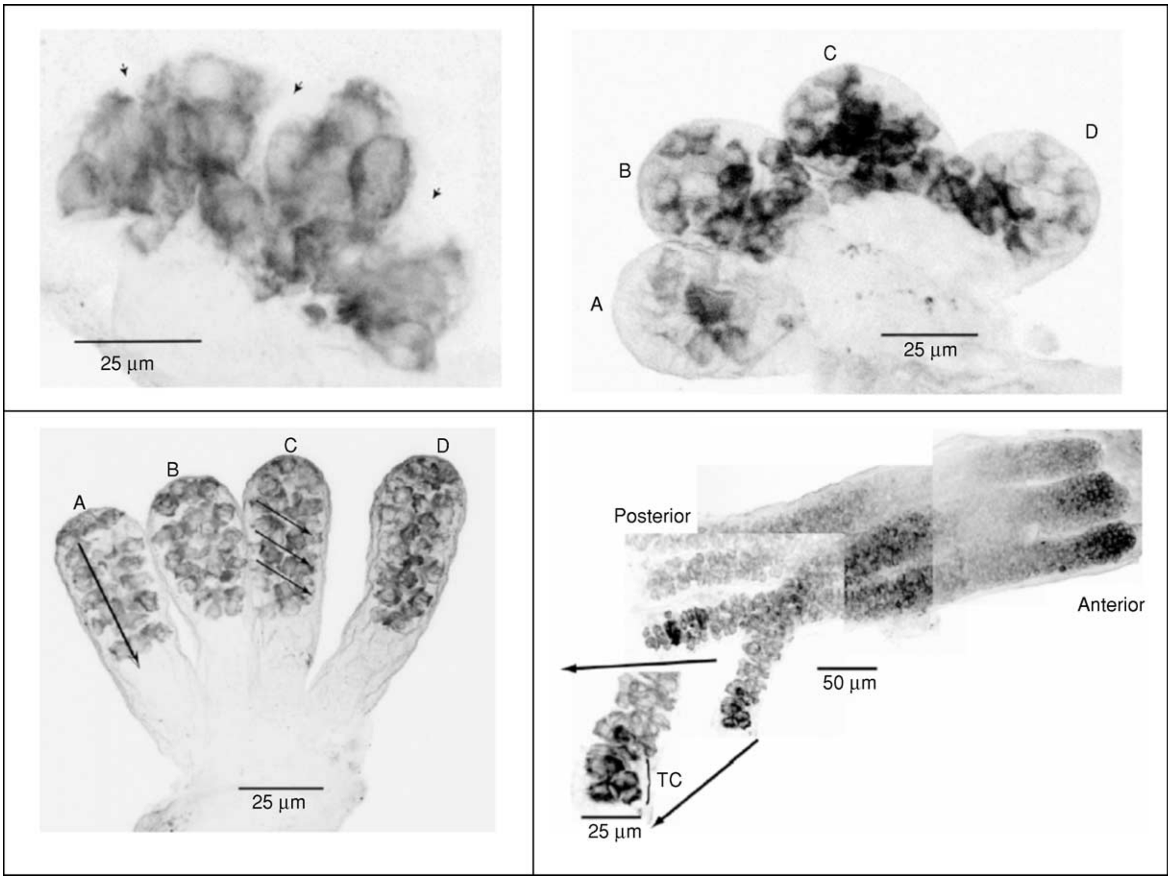

Figure 3 Upper left: a gonad from a late first instar *Plodia* larva immuno-fluorescently stained with α-crystallin (αcp25) antibodies. Somatic tissue segregation of the founding germ cells into separate ovarioles is apparent (marked by arrow heads). The confocal image is a compilation of optical sections through the specimen. Upper right: a gonad (ovary) from an early second instar *Plodia* larva stained with the same antibody. Segregation of the gonad into four ovarioles (A, B, C, and D) is complete and the number of cystoblasts has increased from the earlier stages. The confocal image is a compilation of optical sections through the specimen. Lower left: an ovary from a late third instar *Plodia* larva. The number of cystoblasts has increased and the cells show three levels of organization within the ovarioles. The confocal image is a compilation of half the optical sections through the specimen. The separation between the distal-most cluster of germ cells and the other germ cells within each ovariole is maintained. In ovariole A, a central space can be observed that does not contain immuno-fluorescently stained germ cells (paralleled by the half-open headed arrow). In ovariole C, a diagonal alignment of the germ cells can be seen (paralleled by the three arrows). Lower right: An ovary from a newly pupated *Plodia*. The image is a reassembly of three confocal scanning regions that cover the entirety of the ovary. Each region is the compilation of the optical sections through the region. The arrows show a projection of the most posterior or terminal clusters of cystocytes (TC).

apical tip of each ovariole, while the majority of the germ cells are arranged in a spiral around the perimeter of the ovariole. No cystocyte clusters are observed at this stage, however, suggesting that in moths the divisions to form all of the primary cystoblasts occur before the onset of the cystocyte divisions. This is supported by the clear presence of eight-cell cystocyte clusters discernable in the posterior termini of the ovarioles at the end of the last instar (Zimowska *et al*., 1991; Beckemeyer and Shirk, in press).

The division of the cystoblasts and cystocytes in *Plodia* takes a path considerably different than that taken by *Drosophila*, where the primordial germ cells within the germarium give rise to the cystoblasts, which divide to form the 16-cell cystocyte cluster independent of the formation of other cystoblasts and throughout the adult stage (King *et al*., 1968). At the end of the third larval instar in *Plodia*, the divisions necessary to form all of the cystoblasts have taken place. This appears to happen before the three divisions of the cystoblasts to cystocytes begin. Thus, at the end of the third larval instar, the ovary contains all the cystoblasts necessary for the formation of the full complement of eggs that the female will lay during her adult life. Using a comparison to industry, *Plodia* mass-produces each stage of its germ cell/follicle production line before advancing to the next assembly stage, while *Drosophila* takes the on-time supply approach, by producing and assembling all components of a single follicle, given an adequate food supply and before initiating the production of a subsequent follicle.

The presence of the cluster of the seven primordial germ cells at the apical tip of each ovariole, even at the white pupa stage of *Plodia* (**Figure 3**, lower right) (Zimowska *et al*., 1991; Beckemeyer and Shirk, in press), suggests that there is a potential for producing more cystoblasts, even though all cystocyte clusters necessary for adult egg laying are already present. At this stage, however, the follicles are not complete, because no follicular epithelium cells are observed in association with the cystocyte clusters (Zimowska *et al*., 1991). Follicle cells begin to surround each oocyte–nurse cell complex during the ecdysteroid peak that occurs 28–36 h after pupation (Shaaya *et al*., 1993). By comparison, the organization of the ovarioles and germ cells in the early fifth (last) instar larva of *B. mori* (Miya *et al*., 1970) is similar to that observed in the white pupa of *P. interpunctella*, suggesting an even earlier completion of primordial germ cell development in *Bombyx*.

Following the peak of ecdysteroids that occurs during the early pupal stage (Shaaya *et al*., 1993), pharate adult development is initiated, and the terminal follicles become fully differentiated within the ovarioles of *Plodia* (Zimowska *et al*., 1991). The progress of the female toward the initiation of vitellogenesis is regulated by the declining levels of the ecdysteroids (Shirk *et al*., 1990). After final assembly by 36 h post-pupation, the follicles remain in a pre-vitellogenic state until 92 h after pupation. After this time, the physiology of the female shifts to vitellogenesis, and each ovariole contains a linear array of sequentially developing follicles (**Figure 1**).

1.3.3. Vitellogenesis

During vitellogenesis, the growth of the oocyte in the ovarian follicle accelerates relative to that of the nurse cell complex (Büning, 1994). Growth of the oocyte is enhanced via endocytosis of yolk proteins, which may be derived from two sources, the fat body (vitellogenins) and the follicular epithelial cells that surround the oocyte–nurse cell complex (Raikhel and Dhadialla, 1992; Izumi *et al*., 1994; Melo *et al*., 2000). The oocyte surface is not directly exposed to the hemolymph but is separated from it by the follicular epithelium. Wide channels form between the epithelial cells, a condition termed patency (Telfer *et al*., 1982; Raikhel and Lea, 1991; Davey, 1993; Zimowska *et al*., 1994), allowing passage of hemolymph-derived proteins through the follicular epithelium toward the oocyte surface and into the oocyte.

1.3.3.1. The Transition from Previtellogenesis to Vitellogenesis

In this section, the hormonal control of the transition from previtellogenesis to vitellogenesis in the insects, mostly Diptera and Lepidoptera is discussed, that have been most intensely investigated, including the fruit fly *D. melanogaster*, the yellow fever mosquito, *Aedes aegypti*, and the silkmoth, *B. mori* is discussed. In these three insects, most of the data addressing the mechanism of action of hormones (predominantly ecdysone) in the ovarian tissue, has accumulated. The regulation of the transition in other insects will be only briefly discussed, using the models above as a basis for comparisons and, wherever possible, emphasis will be given to the molecular mechanisms controlling ovarian follicle development.

1.3.3.1.1. Dipteran insects

1.3.3.1.1.1. **Drosophila melanogaster** In *Drosophila*, previtellogenic growth of follicles, corresponding to stages 1–7 of egg chamber (follicle) development, is initiated at the end of adult development, while vitellogenesis (corresponding to stages 8–10) starts after eclosion. The initiation of

vitellogenesis constitutes a control point of oogenesis that integrates internal (hormonal) and external (environmental) signals, to allow efficient progression of follicle development (Spradling, 1993).

1.3.3.1.1.1.1. JH and ecdysone physiological data Hormonal control of vitellogenesis in *Drosophila* is complex and requires both JH (see **Chapter 3.7**) and ecdysteroids (Riddiford, 1993). JH stimulates yolk protein (YP) synthesis in the ovary, and is necessary for the continuation of development of stages 8 and 9 vitellogenic follicles (Jowett and Postlethwait, 1980; Wilson, 1982; Bownes *et al.*, 1988a). In addition, JH stimulates the production of ovarian ecdysteroids (Schwartz *et al.*, 1989).

Ecdysteroids play (see **Chapters 3.3**, **3.4**, and **3.7**) both positive and negative roles in the control of vitellogenesis. In diapausing female adults, oogenesis is arrested shortly before vitellogenesis but can be relieved by the application of 20-hydroxyecdysone (20E) (Richard *et al.*, 1998). Based on this and other observations, it was proposed that in the early stages following adult eclosion, ecdysteroids derived from the ovary or from other sources (Bownes, 1989) stimulate YP synthesis in the fat body as well as YP uptake by the oocyte (Richard *et al.*, 1998).

During the later stages of oogenesis, alternatively, 20E has a negative effect on follicle development. In virgin females, 20E induces apoptosis, causing the disappearance of nearly all vitellogenic follicles, and this effect can be counteracted by administration of JH or sex peptide (SP; Soller *et al.*, 1999). The SP is a 36 amino acid long peptide synthesized by the accessory glands of *Drosophila* males, and transferred to the female fly during mating (Chen *et al.*, 1988; Kubli, 1996) (see also **Chapters 1.5** and **3.9**). It acts on the corpora allata (CA) to stimulate the production of JH (Moshitzky *et al.*, 1996), which, in turn, prevents the 20E-dependent induction of apoptosis in vitellogenic follicles. Thus, a correct balance between JH and ecdysteroids seems to be essential for the progression of vitellogenic follicle development in the *Drosophila* ovary (Soller *et al.*, 1999; Gruntenko *et al.*, 2003). The induction/prevention of apoptosis by 20E/JH shows strict developmental regulation and is restricted to follicles of stage 9, while follicles of earlier or later stages (stages 8 and 10, respectively) are not affected.

1.3.3.1.1.1.2. Genetic analysis role for ovarian ecdysone? Genes implicated in the ecdysone regulatory hierarchy show stage-specific expression patterns during *Drosophila* oogenesis. The levels of the mRNAs for the nuclear receptor E75 and the E twenty-six (ETS) domain-containing transcription factor E74 become upregulated at stage 8 (beginning of vitellogenesis) and peak in abundance at stage 10B (end of vitellogenesis), in both the nurse and the follicular epithelium cells (Buszczak *et al.*, 1999). The E74 and E75 transcription factors function as primary response genes in the ecdysone regulatory cascade that is triggered at the beginning of metamorphosis (Thummel, 1996). Another primary ecdysone-responsive gene, which encodes the various Broad-Complex (BR-C) zinc finger protein-containing transcription factor isoforms, is also induced in the cells of the follicular epithelium during stages 5 and 6, and its expression continues throughout vitellogenesis (Deng and Bownes, 1997). Furthermore, both components of the ecdysone receptor heterodimer, EcR and USP, are expressed throughout oogenesis in both the germline (nurse cells and oocyte) and the soma (follicular epithelium cells) (Khoury-Christianson *et al.*, 1992; Buszczak *et al.*, 1999; Carney and Bender, 2000). Finally, the expression of *E75* and *BR-C* in the ovarian follicles seems to be sensitive to the levels of 20E: higher expression is observed when 20E is added to ovarian cultures, while lower expression occurs at the restrictive temperature in *ecdysoneless* (*ecd*) mutant flies (Buszczak *et al.*, 1999).

Follicles that are germline clones of *E75* and *EcR* show developmental arrest and degeneration at stages 8–9 (Buszczak *et al.*, 1999). A similar arrest in oogenesis was also observed for germline clones of the *dare* gene, which encodes the *Drosophila* homolog of adrenodoxin reductase, an enzyme implicated in steroid hormone biosynthesis (Buszczak *et al.*, 1999; Freeman *et al.*, 1999). Characterization of temperature-sensitive *ecdysoneless*^{1} (*ecd*^{1}) mutants, which have low ecdysteroid levels at the restrictive temperature, also indicate that 20E may be required for the progression of oogenesis beyond stage 8 (Audit-Lamour and Busson, 1981; Walker *et al.*, 1987). Because *dare* is expressed in the nurse cells, it was proposed that *dare* is involved in ecdysone biosynthesis carried out by the nurse cell complex.

Based on the analysis of the available mutants and the expression pattern of genes implicated in ecdysone biosynthesis and the ecdysone regulatory hierarchy during oogenesis, a model was proposed in which ecdysteroids, produced by the germline oocyte–nurse cell complex at the beginning of vitellogenesis, act in an autocrine manner (i.e., within the developing follicle) to activate the ecdysone regulatory cascade. The activation of the ecdysone regulatory cascade is considered necessary for the subsequent progression of oogenesis (vitellogenesis)

beyond stages 8 and 9 (Buszczak *et al.*, 1999; Freeman *et al.*, 1999).

1.3.3.1.1.1.3. Integration of physiological and genetic data From the discussion above, it is clear that much work still needs to be done, in order to elucidate the precise role of ecdysone in the regulation of vitellogenesis in *Drosophila*. In particular, conflicting data exist between the results obtained from the physiological and genetic experiments that requires resolution. Indeed, the physiological experiments suggest that 20E stimulates previtellogenic growth, while it induces apoptosis of vitellogenic follicles (Richard *et al.*, 1998; Soller *et al.*, 1999; Gruntenko *et al.*, 2003), and that a correct balance between ecdysteroids and JH is required for the progression through vitellogenesis (Soller *et al.*, 1999). The genetic studies, alternatively, indicate a requirement for genes such as *EcR*, *E74*, *E75*, and *BR-C* in the transduction of the 20E response during metamorphosis (Buszczak *et al.*, 1999; Carney and Bender, 2000). However, the fact that the *EcR*, *E74*, *E75*, and *BR-C* genes are involved in the control of oogenesis (vitellogenesis), does not necessitate that the regulatory pathway initiated by the hormone 20E is actually involved in this process. In fact, the data that support the model of autocrine control of follicle development progression, by the induction of the required regulatory cascade by 20E, may not be entirely conclusive.

Thus, the function of the *dare* gene may not be entirely limited to ecdysone biosynthesis, but could instead be involved in the catalysis of other enzymatic reactions. Of relevance to this is previous research in other insects, which has shown that the cells of the follicular epithelium, rather than the nurse cell complex, are involved in ecdysone biosynthesis (Lagueux *et al.*, 1977). This has been confirmed through the expression pattern of the *disembodied* (*dis*) gene, which encodes a specific hydroxylase in the ecdysone biosynthetic pathway (Warren *et al.*, 2002) and is expressed in the follicular epithelium (Chávez *et al.*, 2000). The differential expression pattern suggests that the DARE and DIS enzymes are involved in distinct biosynthetic pathways. Therefore, it would be interesting to examine whether mutant clones for the *dis* gene (in the follicular epithelium) would affect the progression of vitellogenesis. Additonally, the fact that mutations of the *E75*, *E74*, *EcR*, and *BR-C* genes affect the progression of vitellogenesis, does not necessarily imply that the ecdysone regulatory pathway is involved. The expression of these genes could be regulated by other pathways. For example, during oogenesis, the expression of the *E75* and *BR-C* genes is controlled by the epidermal growth factor (EGF) pathway during oogenesis (Deng and Bownes, 1997; Buszczak *et al.*, 1999). Furthermore, the requirements for *EcR* may reflect the function of this receptor as a repressor rather than as a ligand(20E)-dependent activator.

In view of these reflections, the view presented by the physiological experiments is favored, i.e., that 20E may be involved in the stimulation of previtellogenic growth but causes apoptosis in vitellogenic follicles. In addition, although genes implicated in the ecdysone regulatory pathway (*E75*, *E74*, *EcR*, and *BR-C*) are required for sustainance of vitellogenic growth, these genes may very well be induced and act in an ecdysone-independent manner.

1.3.3.1.1.1.4. Nutritional control through the insulin signaling pathway The quality of nutrition (absence/presence of protein diet) has profound effects on the rate of follicle development during oogenesis, which can vary by as much as 60-fold (Drummond-Barbosa and Spradling, 2001). Variations in the rates of follicle development are due to differences in rates of cell proliferation in both the germline and the follicle cell lineage, as well as to the different frequencies of cell death at two developmental stages, first, during egg chamber or follicle assembly, when the region of the germarium containing the germline cysts are engulfed by the precursors of the follicle cells, and, second, at the time of initiation of vitellogenesis (stage 8 of follicle maturation; Drummond-Barbosa and Spradling, 2001) (see also **Chapter 1.2**).

The insulin signaling pathway is conserved between *Drosophila* and vertebrates (Edgar, 1999), and *Drosophila* mutants for components of this pathway show a growth-deficiency phenotype (Garofalo, 2002). Mutants for the *Drosophila* insulin receptor, the insulin receptor substrate (IRS)-like gene *chico*, and the ribosomal protein S6 kinase homolog also show female sterility due to poor ovarian growth (Chen *et al.*, 1996; Böhni *et al.*, 1999; Montagne *et al.*, 1999). These results suggest that the insulin signaling pathway is functional in the ovaries. Furthermore, the effects of nutrition on oogenesis are mediated through the insulin pathway. Thus, even in the presence of abundant nutrients, mutations in *chico* partially impair the increase in the proliferation rate of the follicular cells and almost completely prevent the progression of the follicles into vitellogenic stages (Drummond-Barbosa and Spradling, 2001).

Seven insulin-like peptide sequences have been identified in the *Drosophila* genome (DILPs), which show specific and unique patterns of expression in a variety of tissues, including the cells of the ovarian follicular epithelium (Brogiolo *et al.*, 2001; Ikeya

et al., 2002). The expression levels of DILPs in the brain respond to variations in nutrition, and overexpression of DILP2 results in an increase in body weight and organismal size (Brogiolo *et al.*, 2001). The picture that emerges is that signals generated by high nutrition levels result in the release of DILPs from neurosecretory cells at the corpora cardiaca (CC) of the ring gland (Leevers, 2001); DILPs secreted in the hemolymph subsequently stimulate cell proliferation and growth. At the level of the ovary, DILPs are proposed to increase the proliferation rate of the follicular cells and promote the transition from previtellogenesis to vitellogenesis. Furthermore, the expression of DILP5 in follicular cells of vitellogenic follicles (Ikeya *et al.*, 2002) also suggests the existence of a parallel autocrine/paracrine pathway that regulates follicle growth and maturation.

With respect to the possible conservation of the signaling systems that regulate reproduction in insects and vertebrates, it is also worth mentioning that two orphan G protein-coupled receptors (GPCRs) have been identified in the *Drosophila* genome, which are homologs of the mammalian follicle stimulating hormone (FSH), luteinizing hormone (LH), and thyroid stimulating hormone (TSH) receptors (Hauser *et al.*, 1997; Eriksen *et al.*, 2000). However, no data exists for addressing the possible involvement of these receptors in the regulation of insect reproduction. In fact, flies mutant for one of these receptors die at the time of hatching, thus implicating this receptor in the control of embryonic development (Eriksen *et al.*, 2000). Moreover, no FSH, LH, or TSH-like hormones could be identified in the *Drosophila* genome and, consequently, the two orphan *Drosophila* GPCRs may have other types of peptides as ligands (De Loof *et al.*, 2001).

1.3.3.1.1.2. **Aedes aegypti** In contrast to the Lepidoptera (discussed in Section 1.3.3.1.2 below) and *Drosophila*, vitellogenesis and follicle maturation in female mosquitoes occur synchronously following a blood meal (Raikhel and Lea, 1990). At the time of adult eclosion, each ovary consists of the germarium and one follicle per ovariole. JH is required for the follicle to mature to a resting stage, at which time it becomes competent to respond to a blood meal and initiate vitellogenesis (Bownes, 1986). Vitellogenesis consists of two phases, first, of an initiation phase (immediately after the blood meal), during which the cells of the follicular epithelium resume mitosis and separate from the oocyte, while low levels of vitellogenins are produced by the ovary and, second, of a trophic phase (starting 5–6 h after the blood meal), during which the fat body produces large amounts of vitellogenins, and rapid growth of the follicle occurs in the ovary (Riehle and Brown, 2002).

During the initiation phase, neurosecretory hormones, termed egg development neurosecretory hormones (EDNHs) or ovary ecdysteroidogenic hormones (OEHs), are released from the brain and stimulate ecdysteroid production by the ovary (Brown *et al.*, 1998; see also **Chapters 1.5** and **3.9**). The ecdysteroids released from the ovary subsequently initiate the trophic phase by acting on the fat body and stimulating the first vitellogenic cycle (Deitsch *et al.*, 1995; Zhu *et al.*, 2000). Ecdysteroids have also been proposed to be involved in a feedback mechanism that causes the pinching off of the second follicle from the germarium and the shutdown of the high synthetic activity in the fat body at the end of the cycle (Bownes, 1986).

As is the case with *Drosophila*, the insulin signaling pathway is involved in the regulation of ovarian growth (vitellogenesis). Mosquito ovaries contain high levels of the mosquito insulin receptor homolog (MIR; Graf *et al.*, 1997). MIR is expressed in both the nurse and the follicular epithelium cells of the maturing follicles, and its expression levels in the cells of the follicular epithelium increase during the first phase of vitellogenesis (Helbling and Graf, 1998; Riehle and Brown, 2002).

Interestingly, the ovarian MIR can be stimulated by micromolar quantities of bovine insulin, a finding that allowed the elucidation of the signaling pathway in some detail. Bovine insulin was shown to be capable of stimulating tyrosine phosphorylation in the ovary (Riehle and Brown, 2002), and the downstream signaling was shown to involve the phosphatidyl-inositol 3-kinase (PI3K) and protein kinase B (PKB) pathways, but not that of the mitogen-activated protein kinase (MAPK) (Riehle and Brown, 1999, 2003). Furthermore, the action of bovine insulin results in the biosynthesis and release of ecdysteroids by the ovary (Riehle and Brown, 1999). Thus, insulin-like peptides have the same effect on ovarian tissue as the OEH hormones. To what extent the transduction pathways of these two types of hormones overlap or are integrated is unknown at present.

Although the ovary itself is not considered to be a direct target for 20E (Bownes, 1986), data exist with respect to the expression of ecdysone-responsive genes in the mosquito ovary. Of particular interest is the differential accumulation of various *usp* mRNA isoforms during previtellogenesis and vitellogenesis (Wang *et al.*, 2000). During previtellogenesis, the mRNA for the A-isoform predominates, but this isoform becomes rapidly downregulated within 1 h after a blood meal, and the decline persists throughout

vitellogenesis. The mRNA for the USP-B isoform, alternatively, shows an opposite pattern of expression, becoming induced in the ovary after the blood meal. In addition, the expression of *EcR* mRNA increases at the initiation of vitellogenesis (Cho *et al.*, 1995; Wang *et al.*, 2000). Relevant to the differential regulation of target genes in follicular cells may be the observation that EcR/USP-B complexes bind more strongly than EcR/USP-A ones to target sites in the DNA, and are also stronger transcriptional activators in heterologous systems (Wang *et al.*, 2000).

The expression patterns of mRNAs for early and early–late ecdysone response genes (*E75A*, *E75B*, *E75C*, *HR3*, and *E74B*) are nearly identical to that of the vitellogenin receptor (*VgR*) gene, suggesting a function for these genes in the regulation of vitellogenesis in the ovary (Pierceall *et al.*, 1999; Kapitskaya *et al.*, 2000; Sun *et al.*, 2002). Although of unknown functional relevance, the B isoform of the mosquito HNF-4 nuclear receptor (see also discussion on lepidopteran HNF-4 expression below) is also present in ovarian tissue, and its expression is induced following a blood meal (Kapitskaya *et al.*, 1998).

Taken together, these results suggest that genes historically implicated in the ecdysone response have an expression pattern consistent with their having roles as regulators of vitellogenesis in the ovary. Whether the expression of these genes in the ovary is regulated by ecdysteroids, however, remains to be investigated. As was discussed for the case of *Drosophila* (Section 1.3.3.1.1.1.3), the expression of the "ecdysone response" genes may be under the control of other signal transduction pathways.

While uncertainty exists in the case of ovarian tissue, the induction of early and early–late response genes by 20E in the fat body has been demonstrated beyond doubt, and additional data suggest that the regulatory cascade induced by 20E in the fat body of the adult female shows great resemblance to the cascade induced by 20E in other tissues during metamorphosis (Raikhel *et al.*, 1999; Li *et al.*, 2000; Zhu *et al.*, 2000).

1.3.3.1.2. Lepidoptera Lepidopterans can be grouped in different categories based on their dependence for ovarian follicle maturation on metamorphic events (Ramaswamy *et al.*, 1997). The silkmoth *B. mori* exemplifies the first category, in which follicle development is dependent on 20E, occurs during pupal and adult development, and is completed before the emergence of the adult. The second category, is typified by the Indian meal moth, *P. interpunctella*, in which vitellogenesis is triggered by the declining titers of ecdysteroids during adult development (Shirk *et al.*, 1992). Follicle development in this category is also completed before adult eclosion. In a third category, exemplified by the tobacco hornworm, *M. sexta*, initiation of vitellogenesis during metamorphosis is independent of ecdysteroids (Satyanaryana *et al.*, 1994), while choriogenesis is controlled by JH and completed in the adult moth (Nijhout and Riddiford, 1974).

In other lepidopterans such as *Heliothis virescens* (fourth category), the initiation and completion of vitellogenesis and choriogenesis are independent of metamorphic events, with follicle development being initiated in adults and completely dependent on JH (Zeng *et al.*, 1997). Finally, an additional version of hormonal control has been described recently in the fall armyworm, *Spodoptera frugiperda* (Sorge *et al.*, 2000). In the adults of this species, JH is crucial for the regulation of the incorporation of yolk proteins in vitellogenic follicles, and for the induction of ecdysteroid production by the ovary, in a manner reminiscent of the one occurring in *Drosophila*. Ecdysteroids produced by the ovary in turn regulate the production of vitellogenins by the fat body (Sorge *et al.*, 2000).

***1.3.3.1.2.1.* Bombyx mori** In *Bombyx*, oogenesis occurs almost exclusively during pupal and pharate adult development and is completed before adult eclosion (Tsuchida *et al.*, 1987). The moulting hormone 20E was shown to be essential and sufficient for initiating previtellogenic and vitellogenic development in ovarian follicles. Thus, when late spinning larvae are ligated between the thorax and the abdomen, 20E that is produced by and secreted from the prothoracic glands is prevented from entering the abdominal cavity, and developmental arrest ensues. Adult development, including ovarian development, can be induced in the arrested abdomens by injections of microgram quantities of 20E (**Figure 4**) (Tsuchida *et al.*, 1987; Swevers and Iatrou, 1999).

The other major hormone that regulates development in insects, JH, has not been found to be involved in the stimulation of ovarian development in *Bombyx*. Thus, allatectomy of the 4th instar larvae does not prevent ovarian development and egg maturation (vitellogenesis and choriogenesis) in the resulting precocious pupae, suggesting that JH does not play a role during oogenesis (Izumi *et al.*, 1984).

The rise in ecdysteroid titer, during pupal and pharate adult development, initially results in important morphological changes in the ovarian structure. The ovarian capsule, in which the ovarioles are assembled and enclosed during larval and pupal development, ruptures and the developing ovarioles emerge gradually in the abdominal cavity (see **Figure 12** below) (Yamauchi and Yoshitake,

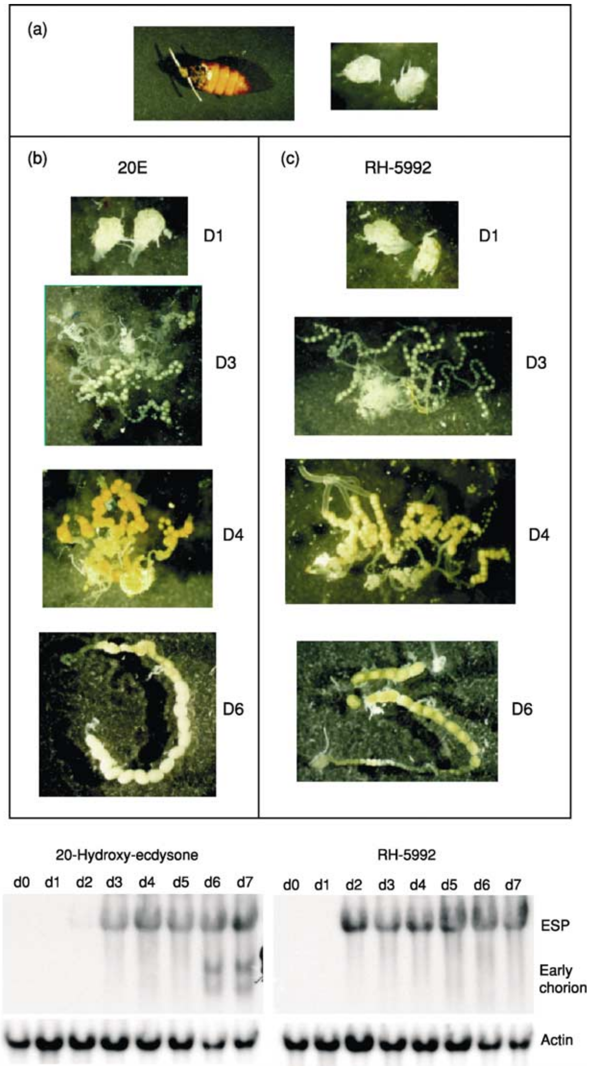

Figure 4 The nonsteroidal ecdysone agonist RH-5992 (tebufenozide) induces ovarian development (previtellogenic growth and vitellogenesis) in the silkmoth, *Bombyx mori*, that is followed by developmental arrest prior to choriogenesis. Upper panel: photographs of a developmentally arrested abdomen (panel (a), left) and of ovaries and ovarioles from abdomens that were either uninjected (panel (a), right), injected with 20E (panel (b)), or injected with RH-5992 (panel (c)). Ovaries and ovarioles are either in dissection medium (panel (a), right, and series D1, D3, and D4 from panels (b) and (c) or mounted in glycerol (D6 in panels (b) and (c). Indicated are the time intervals (in days, D) between injection and dissection. Note that for ovarioles mounted in glycerol, oocytes in choriogenic follicles are prevented from collapsing by the protective eggshell. Color also distinguishes vitellogenic (yellow) from choriogenic (white) follicles. Choriogenic follicles are only apparent in D6 ovarioles from 20E-injected abdomens. Lower panel: expression of egg-specific protein (ESP) and early chorion mRNAs in ovaries at different time intervals (in days, d) following injection of 20E or RH-5992 (tebufenozide) in pupal developmentally-arrested abdomens of *B. mori*. Hybridizing mRNA species in Northern blot analysis are 2 kb (ESP), 0.8 and 0.6 kb (early chorion), and 1.3 kb (actin). Note that ESP mRNA is induced in both 20E- and tebufenozide-injected abdomens, while early chorion mRNA only appears in the former. (Reprinted with permission from Swevers, L., Iatrou, K., **1999**. The ecdysone agonist tebufenozide (RH-5992) blocks progression of the ecdysteroid-regulated gene expression cascade during silkmoth oogenesis and causes developmental arrest at mid-vitellogenesis. *Insect Biochem. Mol. Biol.* 29, 955–963; © Elsevier.)

1984). The removal of the ovarian capsule allows the follicles in the ovarioles to take up yolk proteins from the hemolymph and facilitates their direct exposure to growth factors that are found in it.

At the molecular level, the silkmoth ovary responds to the circulating 20E through the induction of a gene expression cascade that is practically identical to the one observed in other insect tissues (the ecdysone regulatory cascade; Henrich and Brown, 1995; Thummel, 1996). The ovarian tissue expresses the nuclear receptors that constitute the functional ecdysone receptor, which is composed of the heterodimer complex between EcR and USP (Tzertzinis *et al*., 1994; Swevers *et al*., 1995), suggesting that the ovary is a direct target of 20E. Similar to other insect tissues, 20E induces, within a few hours, the

expression of the primary response genes, which encode the nuclear receptors BmHR3 (B and C isoforms) and BmE75 (A and C isoforms) (Eystathioy *et al.*, 2001; Swevers *et al.*, 2002a). During the induction of expression of the mRNAs for these receptors, the mRNA for another nuclear receptor, BmFTZ-F1 (Sun *et al.*, 1994), becomes down-regulated (Swevers and Iatrou, 2003).

The expression of a sixth nuclear receptor, BmHNF-4, is also induced in ovarian tissue (follicular epithelium cells) upon exposure to 20E (Swevers and Iatrou, 1998). In contrast to the BmE75 and BmHR3 receptors, however, the accumulation of BmHNF-4 occurs more slowly and appears to represent a delayed response to the hormone. To date, BmHNF-4 has not been associated with the induction of the ecdysone response in other tissues (Thummel, 1995).

The expression of the yolk protein, egg-specific protein (ESP; Sato and Yamashita, 1991), which is produced by the cells of the follicular epithelium, is initiated approximately two days after larval–pupal ecdysis, when ecdysteroid titers reach peak levels of accumulation in the hemolymph (Tsuchida *et al.*, 1987), and the time of first expression of ESP can be viewed as a timing marker for the initiation of vitellogenesis (Sato and Yamashita, 1991). Moreover, when 20E is injected in developmentally arrested abdomens, ESP expression occurs with similar kinetics as during normal development (2–3 days after injection; **Figure 4**; Swevers and Iatrou, 1999), indicating that ESP expression represents a late response in the ecdysone regulatory cascade. The expression of the *esp* gene does not seem to be directly regulated by 20E, however, because it can occur both during the period of ecdysteroid accumulation to high titers (normal development) and in the *quasi* absence of 20E (developmentally arrested abdomens injected with 20E, in which the hormone is neutralized within 24 h from the injection; Ohnishi and Chatani, 1977).

The expression of two types of transcription factors, BmHR3 and BmGATAβ, shows remarkable changes in abundance in ovarian follicles at the transition from previtellogenesis to vitellogenesis. The A isoform of the nuclear receptor BmHR3 becomes expressed in the cells of the follicular epithelium of vitellogenic follicles (Eystathioy *et al.*, 2001), while there is also a remarkable increase in the accumulation of the mRNAs for the other two isoforms of BmHR3, B and C. The expression of BmHR3 and ESP during vitellogenesis coincides remarkably, and retinoic acid receptor-related orphan receptor response elements (ROREs) capable of binding BmHR3A have been identified in the *esp* gene promoter (Eystathioy *et al.*, 2001), implicating BmHR3A as a potential regulator of *esp* expression (Swevers and Iatrou, 2003). In addition, the expression of the zinc finger-containing transcription factor BmGATAβ (Drevet *et al.*, 1994) is down-regulated during the transition from previtellogenesis to vitellogenesis. In this case, however, immunocytochemistry experiments have shown that expression of BmGATAβ is restricted to the cells of the ovariole sheath rather than the follicular epithelium (Lunke, 2000). Thus, while the expression of BmGATAβ has been correlated with the transcriptional competence of chorion genes (see Sections 1.3.3.3.2 and 1.3.4.1.3), it does not seem to play a role in the differentiation of the follicular epithelium during the transition from previtellogenesis to vitellogenesis. Instead, it may have a specialized (but as yet undefined) role in the ovariole sheath cells that overlay the previtellogenic follicles (Swevers and Iatrou, 2003).

1.3.3.1.2.2. **Plodia interpunctella** Vitellogenesis in *Plodia interpunctella* begins during the pupal stage, which lasts 136 h, and eggs are completely chorionated and ready for fertilization by 6 h after adult eclosion (Zimowska *et al.*, 1991). As is typical of most Lepidoptera, each of the four ovarioles within the ovary contains a linear array of progressively developing follicles, with the most posterior or terminal follicle being the most advanced in development.

During vitellogenesis, oocytes accumulate two major yolk proteins: vitellin (Vn), which consists of two yolk protein (YP) subunits, YP1 ($M_r = 153\,000$) and YP3 ($M_r = 43\,000$), produced and secreted as vitellogenin (Vg) by the fat body cells (see also Section 1.3.3.2 below); and follicular epithelium yolk protein (FEYP), which consists of two subunits, YP2 ($M_r = 69\,000$) and YP4 ($M_r = 33\,000$), produced and secreted by the follicular epithelium cells (Shirk *et al.*, 1984; Bean *et al.*, 1988). The presence of vitellogenin in the hemolymph can be detected by immuno-staining of Western blots with antisera for YP1 or YP3 at 80–83 h after pupation (Shirk *et al.*, 1992). However, Vn cannot be detected by immuno-gold staining with anti-YP1 or anti-YP3 antisera in the terminal follicles until after 112 h after pupation (Zimowska *et al.*, 1994, 1995). Repeated treatments of pharate adult female pupae with 20E leads to the suppression of the oocyte growth and yolk protein accumulation (Shirk *et al.*, 1990), suggesting that the developmental progress of female *P. interpunctella* toward vitellogenesis is regulated by the declining titers of ecdysteroids.

Between the previtellogenic and vitellogenic stages, the terminal follicles enter the provitellogenic stage, during which the follicles become competent to produce FEYP within the follicular epithelium cells, initiate the formation of yolk spheres, and develop patency, the opening of spaces between the follicular epithelium cells that allows penetration of the hemolymph proteins into the oocyte (Zimowska *et al*., 1994). Using immuno-gold staining with anti-YP2 serum, it was established that the follicular epithelium cells begin production of YP2 at 92 h after pupation and, at the same time, the oocytes begin formation of YP2-containing yolk spheres (Zimowska *et al*., 1994). However, none of the other yolk protein subunits is detectable at this time. By culturing early vitellogenic ovaries in varying concentrations of 20E, it was shown that the continuation of YP2 synthesis requires low concentrations of 20E but is inhibited by high levels of the hormone (Shirk *et al*., 1990). These findings suggest that the action of the ecdysteroids is to regulate the progression of vitellogenesis by acting directly on the synthetic activity of the ovarian tissue.

The formation and accumulation of early yolk spheres containing only YP2 and the increased thickness of the brush borders of the follicular cells are both indicators of the progression towards vitellogenesis (Zimowska *et al*., 1994). By 105 h after pupation, the follicular epithelium of the terminal follicles begins to show signs of patency. By 120 h after pupation, full patency is achieved, and both yolk proteins, Vn and FEYP, are accumulated in the yolk spheres (Zimowska *et al*., 1994, 1995; see also Section 1.3.3.2).

1.3.3.1.2.3. Other Lepidoptera While progress has been made regarding the effects of 20E on the silkmoth ovary at the molecular level, no such data exist regarding the hormonal control of vitellogenesis by JH or 20E in the other categories of lepidopterans mentioned earlier. It can be anticipated, however, that regulatory cascades other than the ecdysone cascade are involved. For instance, in the case in which vitellogenesis is triggered by a decline in ecdysteroid titer (*P. interpunctella*; Shirk *et al*., 1992), the involvement of the nuclear receptor FTZ-F1 is expected, since this receptor functions as a competence factor during developmental periods characterized by low ecdysteroid titers (Broadus *et al*., 1999). However, regarding the response to JH, little is known, and a “JH-induced regulatory cascade” has yet to be characterized (Gilbert *et al*., 2000). It remains to be seen to what extent the regulation of vitellogenesis by 20E or JH during follicle development, in lepidopterans belonging to the different categories mentioned above, is carried out by common regulatory factors. It is obvious, however, that no unifying model for the control of the transition from previtellogenesis to vitellogenesis can be proposed at the moment.

1.3.3.1.3. Other insects In other insects where oogenesis has been studied extensively, such as the African migratory locust, *Locusta migratoria*, the cockroaches *Blattella germanica* and *Leucophaea maderae*, and the hemipteran, *Rhodnius prolixus*, JH has been implicated as the major hormone for the control of vitellogenesis (Bownes, 1986; Wyatt, 1991; Davey, 1993; Cruz *et al*., 2003). However, very little information exists with respect to the action of JH in developing follicles at the molecular level. In addition to the action of JH, a few peptide hormones have been also isolated that stimulate or inhibit vitellogenesis (De Loof *et al*., 2001).

The action of JH on ovarian follicle cells has been elucidated to the greatest extent in *R. prolixus* (Davey, 2000). In *Rhodnius*, as in many other insects, JH is essential for vitellogenin uptake by the oocyte. The target cells in the ovary are the cells of the follicular epithelium: the action of JH causes a great reduction in their cellular volumes, and this results in the creation of intercellular channels between the follicular cells (patency), which allows passage of vitellogenin from the hemolymph toward the oocyte surface (Telfer and Woodruff, 2002). At the molecular level, JH acts by binding to an as yet undefined membrane receptor, the subsequent activation of calcium-dependent protein kinase C, and phosphorylation of a polypeptide resembling in size the 100 kDa subunit of Na^+/K^+-ATPase (Sevala and Davey, 1993; Sevala *et al*., 1995). Presumably this leads to a change in the osmotic pressure of the follicular epithelium cells, concomitant shrinkage of their volume, and establishment of patency.

In addition to its action at the membrane level, JH has effects also at the transcription level in the cells of the follicular epithelium. In *B. germanica*, JH stimulates the accumulation of transcripts for the Ca^{2+}-dependent regulatory protein Calmodulin (CAM) in the cells of the follicular epithelium (Iyengar and Kunkel, 1995). The mechanism of action of JH at the level of regulation of gene transcription in the nucleus is unknown at present (Gilbert *et al*., 2000).

In *L. migratoria*, a peptide gonadotropic hormone, called ovary maturating parsin (OMP), has been identified, which is active during the same period of vitellogenesis as JH (Girardie *et al*., 1991; see also **Chapters 1.5** and **3.9**). OMP, however, acts independently of JH, since it is capable of inducing

vitellogenesis in allatectomized animals (Girardie *et al.*, 1996). OMP stimulates vitellogenesis via two distinct hydrophilic domains (Girardie *et al.*, 1998a). On the one hand the C-terminal part presumably acts on ovarian tissue to stimulate ovarian ecdysteroidogenesis, with the produced ecdysteroids subsequently stimulating vitellogenin production by the fat body and concomitant ovarian growth (Girardie and Girardie, 1996; Girardie *et al.*, 1998a). The N-terminal part of OMP, on the other hand, acts on the fat body and stimulates vitellogenin production by increasing its mRNA stability and translatability (Girardie *et al.*, 1998a). The mode of action of either domain of OMP at the molecular level is unknown.

Other peptides derived from neural tissue that may play a role in the regulation of ovarian growth include neuropeptide F-like peptides in locusts and a beetle (Cerstiaens *et al.*, 1999), neuroparsins in locusts (Girardie *et al.*, 1998b; Janssen *et al.*, 2001), and a cAMP-generating peptide in fleshflies (Schoofs *et al.*, 1994). Neuropeptide F-like peptides stimulate ovarian growth and act through GPCRs (Mertens *et al.*, 2002). Neuroparsins, however, have anti-JH effects and are inhibitory to ovarian growth (Girardie *et al.*, 1998b). For both the neuropeptide F-like peptides and the neuroparsins, it is not known whether the ovary is the primary target organ. The cAMP-generating peptide alternatively, has been isolated by its capacity to enhance cAMP production in the ovaries of the flesh fly, *Neobellieria bullata* (Schoofs *et al.*, 1994), but no data exists regarding a correlation between cAMP levels and ovarian differentiation in this species.

Recently, a second type of neuroparsin has been identified in locusts, whose expression in the brain is upregulated during the gonadotropic cycle (Janssen *et al.*, 2001). Because of its expression pattern, this second type of neuroparsin may act as a stimulator, rather than an inhibitor, of ovarian development. It should also be noted that locust neuroparsins show homology to the ovary ecdysteroidogenic hormone (OEH) of the mosquito, which has gonadotropic and ecdysteroidogenic activity on ovarian tissue (Brown *et al.*, 1998; Janssen *et al.*, 2001). As can be hypothesized for mosquito OEH, neuroparsins may function as modulators (negative or positive, dependent on type) of the putative insulin response in locusts.

From the discussion above, it is evident that oogenesis in insects is not regulated by a single, general hormonal mechanism. For all insects, an involvement of at least one of the two major insect morphogenetic hormones, 20E and JH, is apparent. However, the relative contribution of these hormones to the control of oogenesis differs from species to species. Furthermore, the action of 20E or JH in different insect species is exerted on different control points of oogenesis.

More recently, the involvement of neuropeptides in the control of oogenesis could be clearly demonstrated, but again no common "master neuroregulatory circuit" could be identified that is conserved in all insects. This contrasts the situation in vertebrates, where the control of ovarian development is carried out by a conserved set of hormones such as gonadotropins and sex steroids.

1.3.3.2. Ovarian Yolk Proteins

The fat body is the principal site of production of the major yolk protein precursors (YPPs), which are vitellogenin (Vg) in most insects, and yolk peptides (YPs) in cyclorrhaphan (higher) Diptera. It is also the production site of additional YPPs, which are synthesized in a unique fashion in different insect species depending on their life histories and developmental requirements. Remarkably, considering the extreme specialization of this tissue, the fat body of several insects also produces pro-proteases, which are deposited in the developing oocytes. These proteolytic enzymes are involved in the degradation of yolk proteins during embryogenesis.

In most insects, the major protein component of the yolk is vitellin (Vn), the crystallized storage form of Vg. Insect Vgs are large, conjugated proteins. They are translated as primary products with masses of ~200 kDa, which are usually cleaved into subunits (apoproteins) ranging in size from 50 to 180 kDa, although cleavage is not universal (Sappington and Raikhel, 1998b; Maruta *et al.*, 2002; Sappington *et al.*, 2002). Following extensive co- and posttranslational modification, the Vg subunits form high molecular weight oligomeric phospholipoglycoproteins (400–700 kDa), which are secreted into the hemolymph of vitellogenic females (Sappington and Raikhel, 1998b; Tufail *et al.*, 2004). For example, in *P. interpunctella*, the major yolk protein component, Vn, is comprised of two subunits, YP1 ($M_r = 153$ kDa) and YP3 ($M_r = 43$ kDa). It is produced and secreted as Vg by the fat body cells and accumulates in the oocyte during vitellogenesis (Shirk *et al.*, 1984; Bean *et al.*, 1988).

In cyclorrhaphan Diptera such as *Drosophila*, the major YPPs belong to a class of proteins evolutionarily distinct from Vg (Sappington and Raikhel, 1998b; Sappington, 2002), which is not produced at all. Designated "yolk polypeptides" or YPs, they are relatively small proteins (~45 kDa) that are glycosylated, phosphorylated, and sulfated (Bownes and Pathirana, 2002). Interestingly, the YPs of

cyclorrhaphan Diptera are evolutionarily related to *B. mori* ESP and the YP2 subunit of the follicular epithelium yolk protein (FEYP) of pyralid moths, both YPPs that are produced as supplements to Vg (Inagaki and Yamashita 1989; Shirk and Perera 1998; Sappington 2002). They are also homologous to the mammalian triacylglycerol lipase, but lack the functional enzymatic center (Baker and Wolfner, 1988; Bownes *et al.*, 1988b; Terpstra and Ab, 1988; Bownes, 1992).

A number of supplemental proteins have been described that accumulate selectively in developing oocytes. Some of them originate from the fat body and some from the cells of the follicular epithelium. These proteins include both female-specific and bisexually distributed members and, normally, they represent minor components of the yolk. For example, eggs of the stick insect, *Carausius morosus*, contain a minor YP that is secreted by the fat body and sulfated by the follicle cells (Giorgi *et al.*, 1995). However, in a few cases they are almost as abundant as vitellogenin. Thus, in *P. interpunctella*, FEYP, which is comprised of two subunits, YP2 ($M_r = 69$ kDa) and YP4 ($M_r = 33$ kDa), is produced and secreted by the follicular epithelium cells and taken up by the oocyte (Shirk *et al.*, 1984; Bean *et al.*, 1988; see also Section 1.3.3.1.1.2 above). Though not as abundant as Vg, it comprises 25–40% of the yolk protein (Shirk and Perera, 1998). A 30 kDa YPP, called microvitellogenin, is produced by the fat body in *Hyalophora cecropia* and *M. sexta* (Kawooya *et al.*, 1986; Telfer and Pan, 1988; Pan *et al.*, 1994). The fat body of the domesticated silkworm *B. mori* also produces multiple 30 kDa proteins homologous to microvitellogenin (Wang *et al.*, 1989). These proteins are principal components of the hemolymph of both males and females during the late larval and pupal stages of this insect (Izumi *et al.*, 1981). The 30 kDa proteins of *Bombyx* constitute 35% of the egg's total soluble protein, while Vn comprises 40% (Zhu *et al.*, 1986). In *L. migratoria* females, a 21 kDa and a 25 kDa protein are produced by the fat body in synchrony with the synthesis and secretion of Vg (Zhang *et al.*, 1993; Zhang and Wyatt, 1996). These additional YPPs are significant constituents of the yolk in *Locusta* eggs, with the molar concentration of the 21 kDa protein in eggs being close to that of Vn.

Lipids are a critical source of energy during insect embryogenesis (Beenakkers *et al.*, 1985; Van Antwerpen *et al.*, 2004). They represent 30–40% of the insect egg's dry weight (Troy *et al.*, 1975; Kawooya and Law, 1988; Briegel, 1990). Although Vg has a lipid content of 8–15%, its contribution to the total lipid content of the egg apparently is minor (Kawooya *et al.*, 1988; Maruta *et al.*, 2002; Van Antwerpen *et al.*, 2004). The role of lipophorin (Lp), the insect lipid transport protein, in lipid accumulation in insect oocytes is much greater, and was recently reviewed by Van Antwerpen *et al.* (2004). In addition to its role as a lipid carrier, Lp plays a role as a YPP. In saturniid and sphingid moths, Lp is the second most abundant YP behind Vg (Telfer and Pan, 1988). Lipophorin is also present in the yolk of the fall webworm, *Hyphantria cunea* (Yun *et al.*, 1994), and the mosquito *A. aegypti* (Sun *et al.*, 2000).

Biochemical and molecular characterization of two female-specific, fat body-secreted proteins that are deposited in the yolk of *A. aegypti* mosquitoes has revealed that they are proenzymes. The first is a glycosylated 53 kDa protein secreted by the female fat body and accumulated in the developing oocyte in synchrony with Vg (Hays and Raikhel, 1990; Snigirevskaya *et al.*, 1997a). Analysis of the deduced amino acid sequence has shown that it is the proenzyme for a serine carboxypeptidase. This stored proenzyme, vitellogenic carboxypeptidase (VCP), is activated during embryogenesis by cleavage to a 48 kDa polypeptide (Cho *et al.*, 1991). The second protein, a 44 kDa fat body product with sequence similarities to vertebrate cathepsin B, is also incorporated into the yolk of *A. aegypti* (Cho *et al.*, 1999). It is converted to a 42 kDa protein after internalization in the developing oocytes, and further reduced to 33 kDa in developing embryos, coincident with the onset of Vn degradation. The 33 kDa peptide exhibits enzymatic properties of a thiol cathepsin B-like protease, and has been shown to degrade purified mosquito Vn; hence it was named vitellogenic cathepsin B (VCB) (Cho *et al.*, 1999).

An acid cysteine proteinase purified from *B. mori* eggs was subsequently named *Bombyx* cysteine proteinase (BCP). It has a broad substrate specificity and hydrolyzes yolk proteins. The proform of BCP accumulates in the hemolymph, suggesting a fat body origin. Indeed, Northern blot analysis clearly showed that *bcp* mRNA is expressed in the fat body (Kageyama and Takahashi, 1990; Yamahama *et al.*, 2004).

In several studied insects, many other proteins are incorporated into the yolk (Telfer, 2002; Masuda *et al.*, 2004). For example, the iron transport protein transferrin (~65 kDa) is selectively deposited in the yolk of the flesh fly, *Sarcophaga peregrina* (Kurama *et al.*, 1995), and a similar protein is deposited in the bean bug *Riptortus clavatus* (Hirai *et al.*, 2000). The hemolymph and oocytes of *R. prolixus* also contain a 15 kDa heme-binding protein (Oliveira *et al.*, 1995). In Lepidoptera, a blue biliprotein

called insecticyanin, a component of larval hemolymph, is deposited in developing oocytes and is present in mature eggs (Chino *et al.*, 1969; Kang *et al.*, 1995). Biliverdin is a chromophore covalently bound to Vg in *Spodoptera litura*, coloring the eggs green or blue, presumably providing camouflage against green vegetation (Maruta *et al.*, 2002). Finally, an arylphorin-like cyanoprotein, which is a hemolymph storage hexamer, also is deposited in eggs of the bean bug, *R. clavatus*, as a YPP (Chinzei *et al.*, 1990; Miura *et al.*, 1994). For more detailed information on insect yolk proteins and their precursors, see Bownes and Pathirana (2002), Sappington *et al.* (2002), Telfer (2002), Masuda *et al.* (2004), Tufail *et al.* (2004), and Yamahama *et al.* (2004).

1.3.3.2.1. Yolk protein gene transcription factors In *Drosophila*, the gene structures of the three yolk protein genes, *yp1–3*, have been elucidated. *Cis*-regulatory elements were determined in the promoter regions, which are necessary for expression in ovarian follicular cells and in the fat body (Logan and Wensink, 1990; An and Wensink, 1995). Almost all studies have focused on the *yp1/yp2* gene pair whose members are divergently transcribed from a common promoter region. Only very recently has the analysis been extended to the unlinked *yp3* gene (Hutson and Bownes, 2003). To date, most studies have focused on the regulation of these genes in the fat body, with only a limited number of studies addressing their regulation in the ovary.

With regard to expression in the ovarian follicular epithelium cells, genetic analysis in transgenic flies identified two enhancer regions, ovarian enhancer 1 (OE1) and OE2, that are located in the intergenic region and the first exon of *yp2*, respectively (Logan *et al.*, 1989; Logan and Wensink, 1990). The OE regions are distinct from the fat body enhancer (FBE) region, which mediates expression of the yolk protein genes in this tissue (An and Wensink, 1995). The *trans*-acting factors that regulate transcription through OE1 or OE2 have yet to be identified.

Biochemical methods, such as gel retardation assays and *in vitro* transcription assays, have revealed two *trans*-acting factors implicated in the regulation of yolk protein expression in follicular cells. The first factor, yolk protein factor 1 (YPF1), is a homolog of the Ku autoantigen that corresponds to the DNA-binding subunit of DNA-dependent protein kinase (Mitsis and Wensink, 1989; Jacoby and Wensink, 1994). YPF1 binds to a 31 bp sequence located immediately downstream of the *yp1* transcription start site; deletion of this site results in a marked decrease in expression levels of *yp1* mRNA, suggesting that YPF1 is a regulator of *yp1* gene expression (Jacoby and Wensink, 1994). The expression of *ypf1* mRNA is upregulated in egg chambers during vitellogenesis and choriogenesis (Jacoby and Wensink, 1994).

The second factor, dGATAb, belongs to the GATA family of transcriptional activators. An ovary-specific isoform of dGATAb is specifically expressed in the follicular epithelium cells and functions as stimulator of yolk protein gene expression through binding to a palindromic GATA element in the intergenic region of *yp1* and *yp2* (Lossky and Wensink, 1995). It has been proposed that dGATAb is not a stimulatory transcription factor by itself, but rather acts through the formation of partnerships with other proteins, presumably the ones that bind the OE1 and OE2 enhancers (Lossky and Wensink, 1995).

In contrast to the fat body, expression of yolk protein genes in the follicular epithelium cells is not dependent on the sex determination hierarchy (Wolfner, 1988). Experiments using a temperature-sensitive mutation of *transformer-2* (*tra-2*), a component in the sex determination hierarchy, have shown that this hierarchy (see **Chapter 1.1**) functions only during the formation of the ovary. Once the ovarian follicle cells have formed, however, expression of female-specific genes (such as the *yp* genes) in the ovary is regulated by tissue (ovary)-specific factors and is independent of the sex determination hierarchy (Bownes *et al.*, 1990).

In *B. mori*, the orphan nuclear receptor BmHR3A is expressed in the cells of the follicular epithelium of vitellogenic follicles concomitant with the expression of the follicle cell-specific yolk protein ESP (see Section 1.3.3.1.2.1), an analog of *Drosophila* YPs (Sappington, 2002). BmHR3A functions as a transcriptional activator in tissue culture cells and a HR3-binding element has been identified within the *esp* promoter (Eystathioy *et al.*, 2001). It should also be noted that the mosquito AaHR3 is expressed in the ovaries during vitellogenesis together with other transcriptional regulators implicated in the ecdysone regulatory hierarchy. Thus, although functional studies are lacking, the data suggest that HR3 may be a regulator of follicle cell yolk protein gene expression in insects.

1.3.3.2.2. Receptor-mediated endocytosis of yolk proteins in insect oocytes

1.3.3.2.2.1. Early studies of yolk protein uptake in insect oocytes Insect oocytes accumulate enormous amounts of yolk protein precursors that are mainly produced by the fat body. In turn, oocytes are extraordinarily specialized for the specific uptake of these proteins. The first observations related

to the specific accumulation of YPPs were made by Telfer (1960) in the developing oocytes of the silkmoth, *Hyalophora cecropia*, while the first interpretation of endocytosis came from electron microscopic studies of the developing oocytes of the mosquito *A. aegypti* (Roth and Porter, 1964). This latter study revealed the presence of a large number of membrane pits and vesicles in the cortical layer of the oocyte cytoplasm of female mosquitoes after a blood meal. Roth and Porter (1964) described a "bristle layer" on the cytoplasmic side of these vesicles, referred to these vesicles as "coated," and attributed their presence to YPP uptake. They also suggested that coated vesicles carrying YPPs lose their bristle coat, form larger vacuoles, and then grow into "protein droplets," the yolk bodies (**Figure 5**).

Numerous electron microscopic studies of developing oocytes in various insect orders have subsequently shown the presence of these vesicular compartments – coated pits, coated vesicles, and uncoated vesicles – in the oocyte cortex, and studies utilizing electron-dense dyes have confirmed Roth and Porter's hypothesis about the role of coated vesicles in protein uptake (review: Raikhel and Dhadialla, 1992).

Various binding and uptake studies have indicated that Vg is internalized via receptor-mediated endocytosis (RME), and have suggested the presence of specific Vg receptors in the oocytes of *A. aegypti* (Raikhel and Dhadialla, 1992; Sappington *et al.*, 1995), *L. migratoria* (Röhrkasten and Ferenz, 1985; Röhrkasten *et al.*, 1989), *Nauphoeta cinerea* (König and Lanzrein, 1985), *Blattella germanica* (König *et al.*, 1988), *R. prolixus* (Oliveira *et al.*, 1986), *M. sexta* (Osir and Law, 1986), and *H. cecropia* (Kulakosky and Telfer, 1987). However, despite these pioneering studies, the mechanisms of endocytosis have been largely elucidated in other systems, by a combination of animal biochemistry and cell biology, and yeast genetics.

1.3.3.2.2.2. General characteristics of receptor-mediated endocytosis Endocytosis is the cellular process of membrane vesicular transport between the plasma membrane (PM) and cytoplasmic membrane compartments, as well as within the intracellular membrane system. Receptor-mediated endocytosis controls many essential cellular activities, including internalization of essential macromolecules, transmission of neuronal, metabolic and proliferative signals, and defense against invading microorganisms (Goldstein *et al.*, 1985; Bu and Schwartz, 1994).

In RME, an extracellular macromolecule (ligand) is recognized by a specific cell surface receptor. Specific recognition results in high-affinity binding between the ligand and the receptor, which, in turn, triggers endocytosis. The endocytic pathway comprises functionally and physically distinct compartments involved in the internalization of the

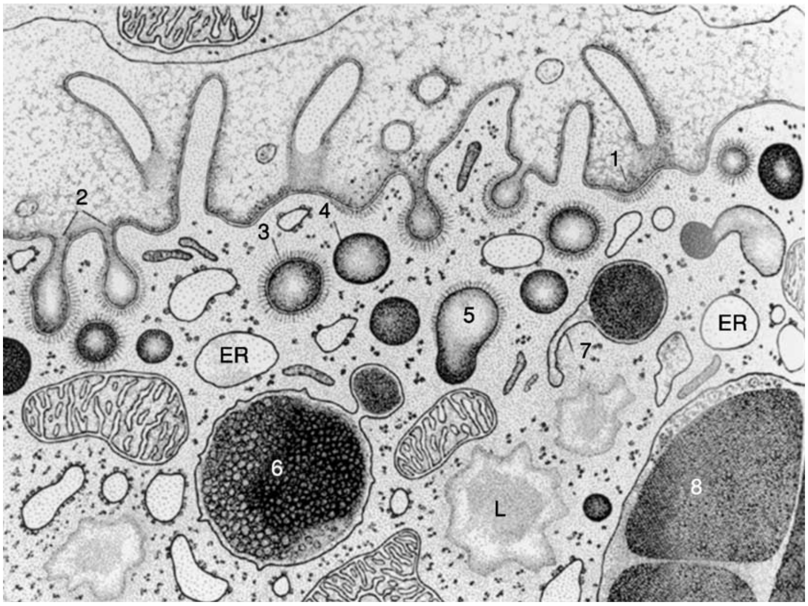

Figure 5 A schematic drawing of protein uptake in the mosquito oocyte: (1) the coated invagination in the plasma membrane of the oocyte; (2) the fully developed coated pit; (3) the coated vesicle; (4) the vesicles after losing their bristles to form dense spheres of similar size; (5) the vesicles fused with other dense spheres; (6) larger droplets coalesced with one another; (7) flattened empty tubular compartment attached to the droplet; (8) larger droplets coalesced to form the large crystalline protein yolk bodies of the oocyte. ER, endoplasmic reticulum; L, lipid droplet. (Reproduced from Roth, T.F., Porter, K.R., **1964**. Yolk protein uptake in the oocytes of the mosquito Aedes aegypti. *J. Cell Biol. 20*, 313–332 by copyright permission of the Rockfeller University Press.)

ligand–receptor complex, the accumulation of ligands, and the recycling of receptors, plasma membrane proteins, and lipids. There are two types of RME, clathrin-dependent and clathrin-independent, defined by the presence or absence of a protein coat on the cytoplasmic side of the vesicular compartments. The main molecular complex of this coat is clathrin (Pearse and Robinson, 1990).

Clathrin-dependent RME, which was first observed in mosquito oocytes, is the major pathway for selective internalization of various macromolecules in insect oocytes through cognate plasma membrane receptors. Goldstein and Brown (1974) were the first to describe RME in mammalian cells and to postulate its general features. In a series of remarkable studies, they characterized the first receptor for RME, the low density lipoprotein (LDL) receptor (LDLR), and identified the pathway for LDL internalization (Goldstein *et al*., 1985). Amongst the other common macromolecular ligands that animal cells internalize by RME, are transferrin (an iron-binding protein), insulin, and most other peptide hormones (Goldstein *et al*., 1979, 1985; Mellman, 1996; Simonsen *et al*., 2001). In insect oocytes, clathrin-dependent RME is responsible for the massive accumulation of Vg and other YPPs (Raikhel and Dhadialla, 1992; Snigirevskaya and Raikhel, 2004). Below, the term RME is used for describing clathrin-dependent RME.

1.3.3.2.2.3. Formation of ligand–receptor complexes, internalization and intracellular fate Receptor–ligand complexes accumulate in coated invaginations of the PM, called clathrin-coated pits (CCPs) (**Figure 6**, A). These invaginations serve to concentrate cargo proteins into the forming vesicles, and provide a mechanical means to deform a membrane into a vesicular bud. During the progressive assembly of clathrin-coated buds and their maturation, the membrane acquires increasing curvature, until a deeply – invaginated coated pit forms (Takei and Haucke, 2001). When this bud matures, it pinches off giving rise to a clathrin-coated vesicle (CCV).

The clathrin coat has been the subject of extensive biochemical characterization (Pearse and Robinson, 1990; Marsh and McMahon, 1999; Brodsky *et al*., 2001). Its basic constituent, the clathrin functional unit, is the triskelion consisting of three 180 kDa clathrin heavy chains (CHCs), each complexed with a 30–35 kDa light chain (CLC) (**Figure 6**, B). When triskelions polymerize, they form a curved structure. It has been calculated that each vesicle consists of

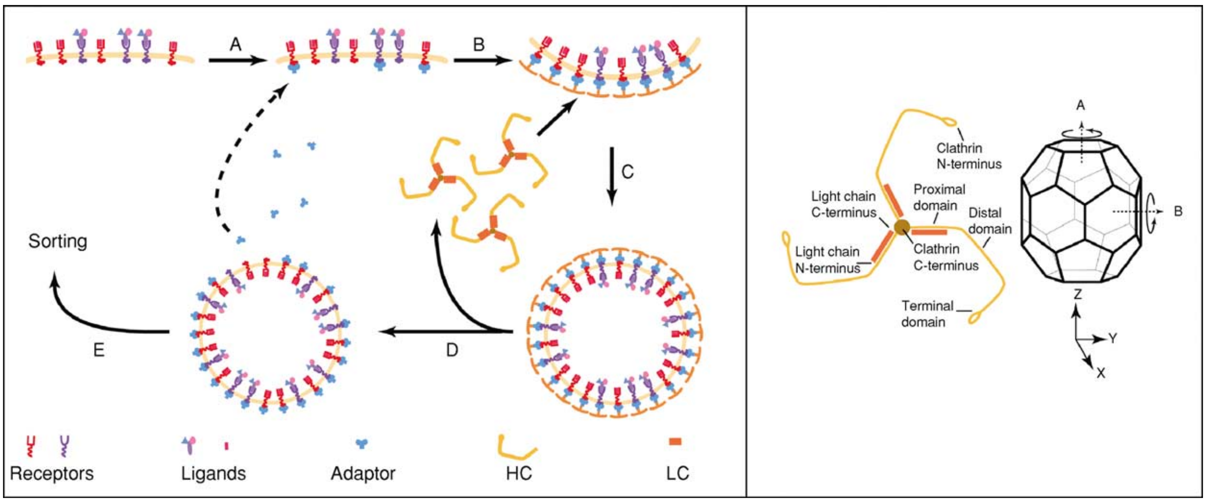

Figure 6 Left panel: early sequential steps of receptor-mediated endocytosis. (A) Receptors are present in the plasma membrane (PM); binding of ligands to their cognate receptors activates recruitment of adaptors that interact with the cytoplasmic domains of receptors. (B) Clathrin triskelions are recruited from the cytoplasmic pool, and assembly of the clathrin lattice on the PM cytoplasmic side is triggered. (C) The clathrin coated vesicle pinches off from the PM and migrates to the cytoplasm. (D) The first step of vesicle uncoating involves detachment of clathrin, which is reutilized for formation of other coated vesicles. In the second step, adaptors are removed and recycled to the PM. (E) The uncoated vesicle fuses with an acceptor compartment, where uncoupling of ligand–receptor complexes and ligand sorting occur. HC, heavy chain of clathrin; LC, light chain of clathrin. (Based on Brodsky, F.M., Chen, C.-Y., Knuehl, C., Towler, M.C., Wakeham, D.E., **2001**. Biological basket weaving: formation and function of clathrin-coated vesicles. *Annu. Rev. Cell Devel. Biol. 17*, 517–586.) Right panel: Schematic diagrams of the clathrin triskelion (left) and the clathrin cage (right). Left: Three clathrin heavy chains (CHC) come together to form a triskelion. The clathrin light chains (CLC) are located at the CHC proximal portions that are being connected at their C-termini. CLCs facilitate triskelion formation. Right: Location of the symmetry axes and the asymmetry unit of the hexagonal clathrin cage. The dashed arrows (A and B) mark the sixfold symmetry axes. The *X*, *Y*, and *Z* axes are defined so that they intersect at the center of the barrel (Smith *et al*., 1998).

60 triskelions assembled into 20 hexagons and 12 pentagons to achieve the curvature of a CCP (**Figure 6**).

An insect CHC has been characterized in the mosquito *A. aegypti* (Kokoza and Raikhel, 1997; Kokoza *et al*., 1997). The authors showed that the *chc* gene spans approximately 45 kb, with its coding region divided into seven exons, five of which encode the protein (**Figure 7**). Three distinct mature *chc* transcripts were identified in various mosquito tissues. Two of them are specifically expressed in female germ-line cells encoding isoforms of the CHC polypeptide (M_r of ~191 500) that differ from each other in their NH_2-terminal sequences. The third transcript has a 3′-untranslated region about 1 kb longer than the other variants, and is found only in somatic cells. Tissue-specific 5′-exon splicing and alternative polyadenylation of the primary transcript combine to give rise to these mRNA variants.

The mosquito CHC isoforms are highly conserved, with full-sequence identities of 88% with *D. melanogaster*, 81% with mammal (rat, cow, and human), 71% with *Caenorhabditis elegans*, 58% with *Dictyostelium discoideum*, and 49% with yeast CHC polypeptides. The highest degree of conservation is in the middle portion of the CHC molecule, which includes the linker region and the extended triskelion arm, with decreasing conservation through the N-terminal domain, trimerization domain, and the relatively diverged C-terminal region.

Polyclonal antibodies raised against a bacterially-expressed AaCHC fusion protein recognized one major band of about 180 kDa in whole vitellogenic ovary lysates, while immuno-gold labeling of the AaCHC polypeptide localized it to the coat of CCPs and CCVs of oocytes of vitellogenic follicles (see below). Finally, Northern blot and *in situ* hybridization analyses have suggested that the regulation of *chc* gene expression in the mosquito ovary is complex, and likely involves both developmental and hormonal signals (Kokoza *et al*., 1997).

After internalization, CCVs rapidly lose their clathrin coats and deliver their contents to early endosomes (EEs), where molecular sorting occurs (**Figure 6**). The assembly and uncoating of CCVs are both energy-dependent processes (Takei and Haucke, 2001). Early endosomes represent a dynamic network of tubules and vesicles dispersed throughout the cytoplasm (Geuze *et al*., 1983a, 1983b; Tooze and Hollinshead, 1991; Wilson *et al*., 1991; Gruenberg and Maxfield, 1995; Mukherjee *et al*., 1997). Their slightly acidic pH (6.0–6.8), which is maintained by an ATP-driven proton pump (Al-Awqati, 1986; Mellman, 1996; Sheff *et al*., 2002), facilitates the dissociation of many of the ligands contained in them from their receptors.

Free receptors accumulate in the EE's tubular extensions (see below) and are recycled back to the PM (Gruenberg and Maxfield, 1995; Mellman, 1996). The vesicular portions of EEs containing the dissociated ligands traverse to the perinuclear

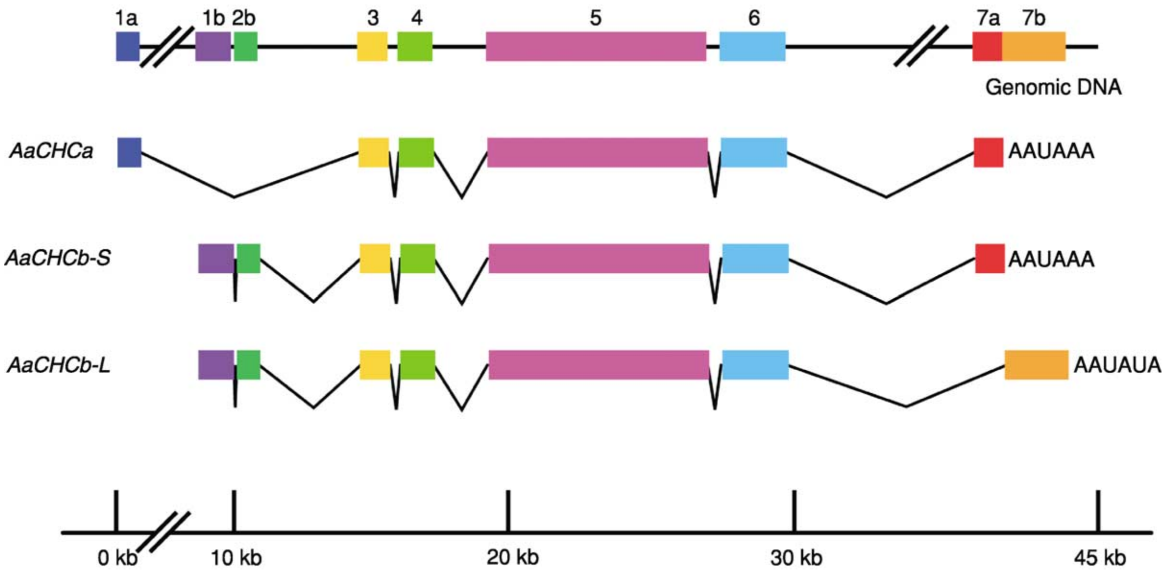

Figure 7 Schematic deduced structure of the *Aedes aegypti chc* gene and its relation to alternatively spliced mRNAs. The *A. aegypti chc* gene is depicted as *boxes* and *lines* representing exons and introns, respectively. Exons are numbered. Three putative transcripts generated from the *A. aegypti chc* gene are shown. Two alternative polyadenylation signals, (AAUAAA) and (AAUAUA), are indicated. (Modified from Kokoza, V.A., Raikhel, A.S., **1997**. Ovarian- and somatic-specific transcripts of the mosquito clathrin heavy chain gene generated by alternative 5′-exon splicing and polyadenylation. *J. Biol. Chem. 272*, 1164–1170, with permission.)

cytoplasm and sort toward late endosomes (LEs) and lysosomes. The LEs accumulate and concentrate internalized contents and partially degraded ligands. From the endosomes, proteins may move to the lysosomes, where they can be degraded by an even lower pH (5.0) and a high concentration of lysosomal enzymes. Some proteins may recycle back to the *trans*-Golgi network or the cell surface for further rounds of transport (Mellman, 1996).

*1.3.3.2.2.4. **Receptor-mediated endocytotic pathways in insect oocytes*** In recent years, many details have been elucidated concerning YPP internalization pathways and specific endocytic compartments in insect oocytes (Raikhel and Dhadialla, 1992; Sappington *et al*., 1995; Sappington and Raikhel, 1995; Snigirevskaya *et al*., 1997a, 1997b; Raikhel and Snigirevskaya, 1998; Snigirevskaya and Raikhel, 2004). These studies have revealed that, in general, the sequential steps of RME in oocytes are the same in different insect species. Furthermore, the cellular organelles involved in oocyte RME are similar to those of somatic cells. However, unique features of RME in developing oocytes include an extraordinarily high level of endocytotic organelles in the oocyte cortex, as well as the final routing of internalized YPPs to specialized accumulation organelles, the mature yolk bodies (MYBs), in which YPPs are only minimally processed and are stored until the onset of embryonic development (Telfer *et al*., 1982; Raikhel, 1984; Raikhel and Dhadialla, 1992; Opresko and Wiley, 1987; Giorgi *et al*., 1993a; Raikhel and Snigirevskaya, 1998; Warrier and Subramoniam, 2002; Snigirevskaya and Raikhel, 2004).

1.3.3.2.2.4.1. Receptor-mediated endocytotic pathway of vitellogenin Most studies have been devoted to the internalization of the major YPP, Vg. Studies, at the electron microscopy (EM) level, particularly those that utilized electron dense tracers, have provided the foundation for our understanding of the ultrastructural morphology underlying the RME of YPPs in insect oocytes (see Telfer *et al*., 1982; Raikhel and Dhadialla, 1992).

The purification of Vgs from different insects facilitated the introduction of immunocytochemical methods at the ultrastructural level. A detailed immunocytochemical study was first conducted using developing oocytes of the mosquito *A. aegypti* (Raikhel, 1984). It was shown that Vg binds only along the lower third of oocyte microvilli and between them, suggesting the presence of Vg-specific receptors (VgRs) in these regions of the ooplasm. In adddition, Vg was localized in the organelles of the endocytotic pathway, the CCPs, CCVs, and uncoated vesicular compartments (Raikhel, 1984).

Vitellogenin receptors were purified from the oocytes of *L. migratoria* (Ferenz, 1993) and *A. aegypti* (Sappington *et al*., 1995), and specific anti-VgR antibodies were raised against them. Vitellogenin receptors have been localized subsequently in the oocyte CCPs and CCVs of these insects (Ferenz, 1993; Snigirevskaya *et al*., 1997a). A similar localization of VgR has been described in other oviparous animals, including the chicken *Gallus gallus* and the crab *Scylla serrata* (Schneider, 1992; Warrier and Subramoniam, 2002).

A detailed EM immunocytochemical study of mosquito oocytes has demonstrated the co-localization of Vg and VgR in compartments of the endocytotic pathway (Snigirevskaya *et al*., 1997a). Following initiation of vitellogenesis, the intracellular spaces in the follicular epithelium dilate, facilitating access of macromolecules to the surface of the oocyte. Vitellogenin and its receptor co-localized to specific microdomains at the base of the oocyte microvilli (Snigirevskaya *et al*., 1997a). They were also present in the same compartments of the endocytotic pathway, the CCPs, CCVs, uncoated small vesicular compartments, and EEs (**Figure 8**). Both Vg and VgR were found close to the membrane of these organelles, suggesting that Vg was still bound to its receptors at these stages of internalization (**Figure 8a**).

Uncoated EEs have been observed fusing with one another as well as with larger vesicular compartments, called transitional yolk bodies (TYBs). However, in the TYBs, Vg is localized predominantly in the lumen. Remarkably, numerous tubular compartments are connected to the TYBs, which also are labeled positively with anti-VgR antibodies but not with anti-Vg ones (Snigirevskaya *et al*., 1997a). The differential localization of the ligand and its receptor clearly indicates that the TYB is the organelle for ligand–receptor dissociation, accumulation of Vg, and receptor recycling via tubular compartments (**Figure 8b**). Similar tubular compartments were observed previously in developing vitellogenic insect oocytes (Telfer *et al*., 1982; Raikhel, 1984 Van Antwerpen *et al*., 1993), but the role of these compartments remained unclear, until the direct EM immunolabeling studies with anti-VgR antibodies were conducted with the *A. aegypti* oocytes (Snigirevskaya *et al*., 1997a).

The TYBs are simultaneously in contact with both Vg-containing EEs and VgR-containing tubular compartments. Thus, these data clearly demonstrate that the dissociation of VgR and Vg occurs in the TYBs during coalescence with the EEs, which serve as sorting compartments in somatic cells.

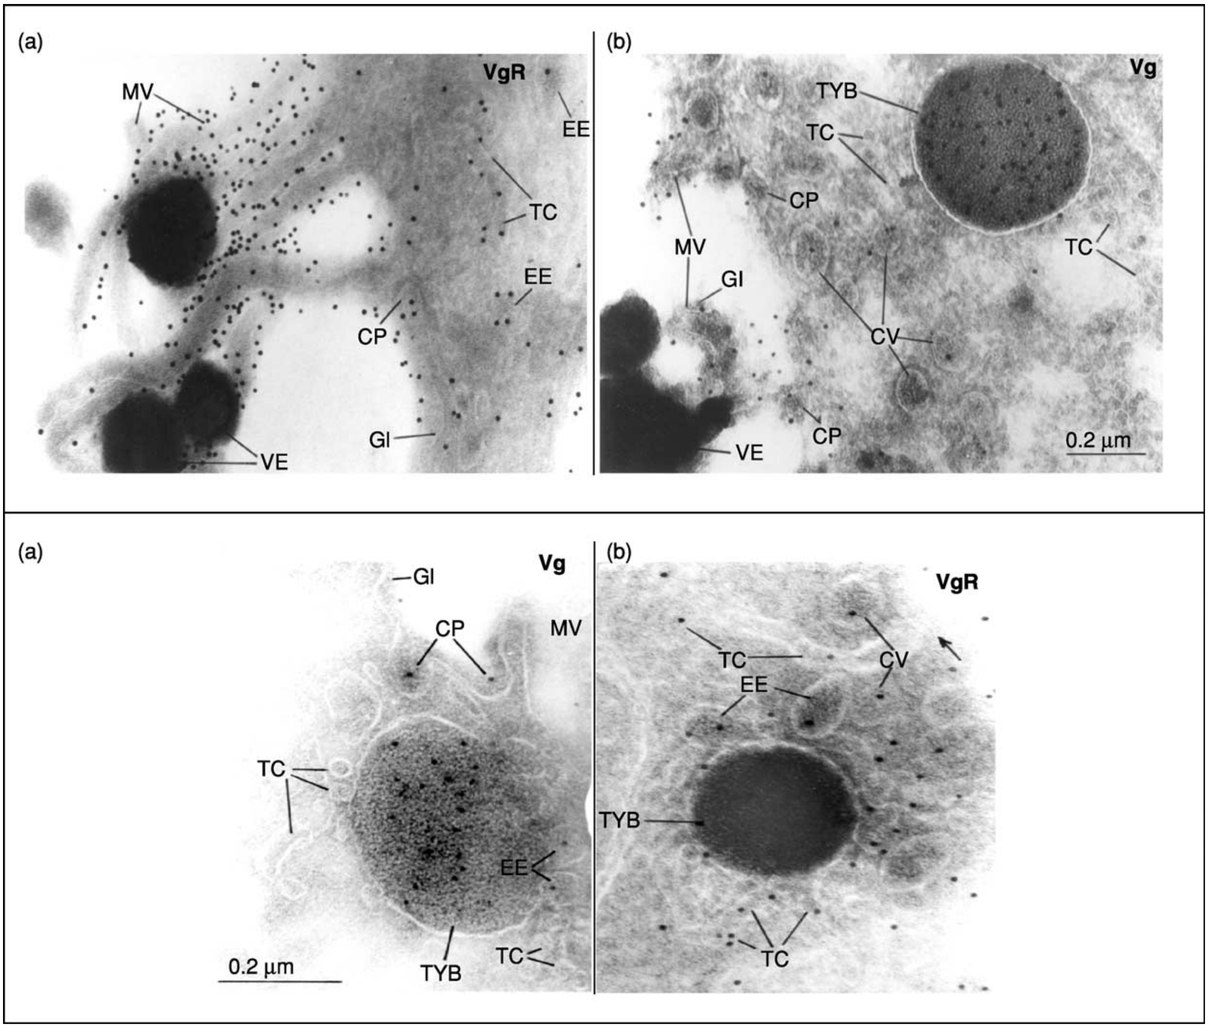

Figure 8 Internalization of vitellogenin (Vg) in the mosquito oocyte visualized through labeling of Vg and vitellogenin receptor (VgR) in ultra-thin frozen sections with 10 nm colloidal gold. Upper panel: The early stages of internalization. (a) Anti-Vg antibodies and protein-gold immunocytochemistry reveals the presence of Vg on the ooplasm membrane at the base of the microvilli (MV), in coated pits (CP), coated vesicles (CV), and the transitional yolk body (TYB), but not in the tubular compartments (TC). (b) Localization of VgR by anti-VgR antibodies and protein-gold immunocytochemistry shows its abundant presence in the oocyte microvillus membrane, CPs, early endosomes (EE), and TCs. Lower panel: The late stages of receptor-mediated endocytosis of vitellogenin in the mosquito oocyte. (a) Anti-Vg antibodies and protein-gold immunocytochemistry reveals the presence of Vg in the lumen of the transitional yolk body (TYB), but not in the tubular compartments (TC). (b) Localization of VgR by anti-VgR antibodies and protein-gold immunocytochemistry shows its abundant presence in TCs. However, in the TYB, VgR label can be found only in TYB membrane. CP, coated pit; EE, early endosome; GL, glycocalyx (surface extracellular coat); MV, microvillus; VE, plaques of the forming vitelline envelope. Scale bar = 0.2 µm. (From Snigirevskaya, E.S., Sappington, T.W., Raikhel, A.S., **1997b**. Internalization and recycling of vitellogenin receptor in the mosquito oocyte. *Cell Tissue Res. 290*, 175–183, with permission.)

Eventually, the TYBs are transformed into mature yolk bodies (MYBs), where vitellin, the crystallized storage form of Vg, is stored (Snigirevskaya *et al*., 1997a, 1997b).

*1.3.3.2.2.5. **Accumulation of nonvitellogenin yolk proteins*** Several yolk protein precursors (YPPs) are deposited in developing insect oocytes. In addition, some other female-specific proteins are important for the development of insect oocytes. However, detailed analysis of their internalization is limited.

1.3.3.2.2.5.1. RME of YPs in Drosophila As mentioned earlier, the YPs of cyclorrhaphan Diptera are small (~45 kDa) glycosylated, phosphorylated, and sulfated (Bownes and Pathirana, 2002). Using the *Drosophila* mutant *yolkless* (*yl*), the gene encoding the YP receptor (Yl) has been cloned and characterized (Schonbaum *et al*., 1995; Bownes and Pathirana, 2002). In wild-type vitellogenic oocytes, the receptor is located at the cortex of the egg, and YPs accumulate through the CCPs (Schonbaum *et al*., 2000).

1.3.3.2.2.5.2. Uptake of lipophorin Lipophorin (Lp) serves as a lipid shuttle between the fat body and the developing oocyte, and in some insects, such as lepidopterans and mosquitoes, is sequestered in the yolk (Kawooya and Law 1988; Sun *et al*., 2000; Telfer, 2002; Van Antwerpen *et al*., 2004). Competition experiments with cultured *M. sexta* ovaries indicate that Vg and Lp are internalized by two different receptors as well (Osir and Law, 1986; Kawooya *et al*., 1988). In *H. cecropia*, however, evidence suggests that only a single receptor is involved in endocytosis of these two ligands (Kulakosky and Telfer, 1990). The Lp receptor (LpR) has been cloned and sequenced from both the locust, *L. migratoria* (Dantuma *et al*., 1999) and the mosquito, *A. aegypti* (Cheon *et al*., 2001; Seo *et al*., 2003).

Transient expression studies using vertebrate cell lines demonstrated that the *Locusta* receptor is capable of mediating the endocytic uptake of the *Locusta* high density lipopoprotein (HDLp), lipophorin (Lp). Sun *et al*. (2000) and Cheon *et al*. (2001) have demonstrated direct binding of mosquito Lp to the LpR. It is uncertain, however, how much of the lipid content of *L. migratoria* and *A. aegypti* eggs is derived from receptor-mediated uptake of Lp by the oocyte. A preliminary estimate of the amount of Lp in *Aedes* oocytes indicates that the contribution of internalized Lp to the lipid reserves of the oocyte is limited (Sun *et al*., 2000), suggesting that an additional mechanism exists for lipid delivery to the oocyte. Van Antwerpen *et al*. (1993) conducted a detailed analysis of developing *M. sexta* oocytes with respect to the endocytic pathway for protein incorporation. Three major (lipo)protein components of the mature eggs of this insect, Lp, Vg, and microvitellogenin, were localized along this pathway by immuno-fluorescence and immuno-gold labeling techniques. Labeling of the antigens was initially observed in the extracellular space of the follicle, and the three YPPs have been detected in CCPs and CCVs near the plasma membrane of the oocyte. All three YPPs were observed subsequently in endosomes in the cortex of the oocyte.

The morphology and labeling patterns of the endosomes indicate that this organelle represents the compartment where uncoupling of the receptor from the ligand takes place. In contrast, tubular elements at the surface of the endosome, interpreted to be involved in the recycling of receptors and membranes to the oocyte surface, were not labeled. Strong labeling of Lp, Vg, and microvitellogenin was observed in the developing yolk bodies, the main protein storage compartment of the oocyte. A similar study conducted on *Aedes* oocytes indicates that Vg and Lp are internalized and trafficked together through the same RME pathway (E.S. Snigirevskaya and A.S. Raikhel, unpublished data). Interestingly, both lipoproteins co-localize in the crystalline portion of MYBs.

1.3.3.2.2.5.3. RME of proenzymes serving as YPPs Localization studies of the female-specific YPPs, vitellogenic carboxypeptidase (VCP) and vitellogenic cathepsin B (VCB), in developing mosquito oocytes, have shown that the internalization of these proteins is performed through the same endocytic pathway as Vg. All three YPPs are found on the oocyte microvillus membrane, in CCPs, CCVs, and EEs, and are also co-localized in TYBs (Snigirevskaya *et al*., 1997b). The study, which was based on immuno-gold EM of the developing oocytes of *A. aegypti*, revealed the co-localization of VCP and VCB in most compartments of the RME pathway, from CCPs to TYBs (Snigirevskaya *et al*., 1997a, 1997b). However, VCP and VCB co-localize in the noncrystalline matrix surrounding the compartment where Vn and Lp accumulate (**Figure 9**).

The VCP and VCB proteins are precursors of enzymes participating in yolk degradation during embryogenesis (Raikhel and Dhadialla, 1992; Sappington and Raikhel, 1995). Mature yolk granules can be viewed as a delayed lysosomal compartment particular to oocytes (Wall and Meleka, 1985; Fagotto, 1995). However, in contrast to somatic cells, oocytes do not contain typical lysosomes. In somatic cells, lysosomal enzymes (hydrolases) are delivered from the Golgi complex and initiate the degradation of most ligands in LEs (Gruenberg and Maxfield, 1995; Mellman, 1996; Mukherjee *et al*., 1997). However, in the oocytes of some animals, the presence of enzymes in yolk granules has been described. The enzymes include β-N-acetylglucosaminidase in *Xenopus* (Wall and Meleka, 1985), and serine proteases and cathepsin B and L in *Drosophila* and *Bombyx* (Indrasith *et al*., 1988; Medina *et al*., 1988; Medina and Vallejo, 1989). Giorgi *et al*. (1993b) have suggested that Golgi-derived vesicles deliver hydrolytic enzymes from the Golgi complex to the yolk bodies.

Thus far, the screening of mosquito ovary cDNA libraries has revealed only two RME receptors, VgR and LpR. Ligand-overlay experiments have suggested that VgR is highly specific for Vg, while LpR binds Lp, VCP, and VCB. While binding of Lp occurs by itself, binding of VCP and VCB requires the presence of Lp. Moreover, in co-immunoprecipitation experiments, both VCP and VCB bind Lp (X. Wu, T. Hiraoka, and A.S. Raikhel, unpublished data). This suggests that Lp serves as a carrier for VCP

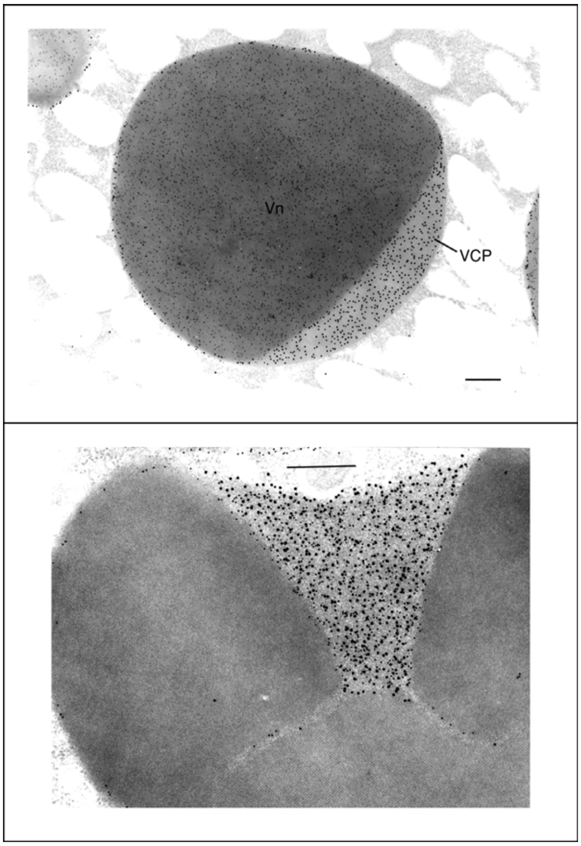

Figure 9 Upper panel: Localization of yolk proteins (vitellin and two processing proteases) in oocyte mature yolk bodies from mosquito females. Double immunolabeling of vitellin (Vn; 10 nm gold particle) and vitellogenic carboxypeptidase (VCP; 15 nm particle) in the mature yolk body of an oocyte from a female mosquito at 24 h post-blood meal. Note the differential localization of these two yolk proteins. Lower panel: Double immunolabeling of vitellogenic carboxypeptidase (VCP; 10 nm gold) and vitellogenic cathepsin B (VCB; 15 nm gold) in the mature yolk body of an oocyte from a female mosquito at 24 h post-blood meal. Note that both these yolk proteins are co-localized in the noncrystalline matrix of the mature yolk body. Bar: 0.5 μm. (Reproduced from Snigirevskaya, E.S., Hays, A.R., Raikhel, A.S., **1997a**. Secretory and internalization pathways of mosquito yolk protein precursors. *Cell Tissue Res. 290*, 129–142, with permission.)

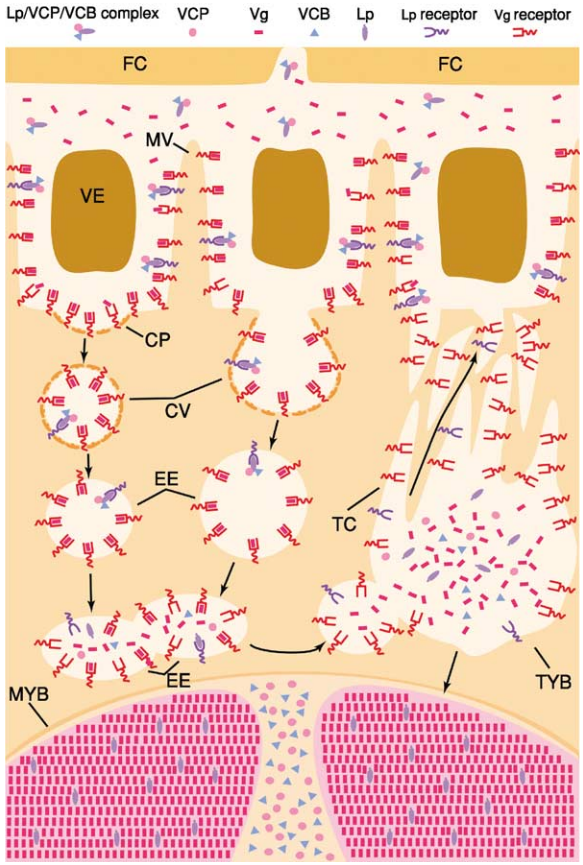

Figure 10 Schematic interpretation of the endocytic pathways and subsequent routing of Vg and VgR, Lp and LpR, VCP and VCB during the internalization of yolk proteins by mosquito oocytes. Ligand–receptor complexes cluster in clathrin-coated pits (CPs) of the vitelline envelope (VE), which invaginate into the cytoplasm and pinch off to form coated vesicles (CVs). VgR binds Vg exclusively, while LpR binds Lp, which presumably transports VCP and VCB via a piggyback mechanism. These complexes are internalized via the same CVs. Upon losing their clathrin coat, the CVs are transformed into early endosomes (EEs), which fuse with one another to form the late endosomes or transitional yolk bodies (TYBs). Early endosomes contain Vg/VgR and Lp/LpR, whereas segregation of the Vg and VgR occurs in the TYBs. Likewise, similar segregation of Lp and LpR is observed. The lumen of the TYB contains four yolk proteins: Vg, Lp, VCP, and VCB. Presumably, Lp, VCP, and VCB are dissociated at this point. VgR and LpR are present only in numerous tubular compartments, which are connected to the TYB and also observed in contact with the ooplasm. The mature yolk bodies (MYBs) contain two parts: the crystalline yolk, composed of modified Vg (vitellin-Vn), and Lp and the non-crystalline matrix, which surrounds Vn/Lp crystals and contains VCP and VCB. (Based on Snigirevskaya *et al*., 1997a, 1997b; E.S. Snigirevskaya and A.S. Raikhel, unpublished data.)

and VCB, and that internalization of these YPPs most likely occurs via a "piggyback" mechanism. The overall picture that has emerged from studies of RME trafficking of YPPs in the mosquito oocytes is presented in Figure 10.

1.3.3.2.3. Oocyte receptors for yolk protein endocytosis

1.3.3.2.3.1. Insect yolk protein receptors Several biochemical studies preceded the cloning and molecular characterization of vitellogenin receptors (VgRs) (reviews: Raikhel and Dhadialla, 1992; Sappington and Raikhel, 1998b). The *L. migratoria* VgR has not been cloned, but its size of 180 kDa was determined on SDS gels (Hafer and Ferenz, 1991). By way of comparison, the mosquito VgR was shown to have a mass of 205 kDa using the ligand-overlay technique (Dhadialla *et al*., 1992; Sappington and Raikhel, 1995).

As of the writing of this chapter, there are only three insects from which cloned VgR sequences have been reported, the yellow fever mosquito, *A. aegypti* (Sappington *et al.*, 1996), the fire ant, *Solenopsis invicta* (Chen *et al.*, 2004), and the cockroach, *P. americana* (Acc. no. BAC02725). A database search of the recently published genome sequence of the malaria mosquito, *Anopheles gambiae* (Holt *et al.*, 2002), yielded a predicted amino acid sequence (Acc. no. EAA06264) with 54% identity to the *A. aegypti* VgR sequence. This will be referred to here as the *A. gambiae* VgR (Sappington and Raikhel, 2004).

There is no evidence for Vg production or Vg genes in cyclorrhaphan flies like *Drosophila*, which instead utilize smaller unrelated YPs as their major yolk proteins (Bownes and Pathirana, 2002). The YP receptor in *D. melanogaster* was identified and cloned by taking advantage of the *yolkless* (*yl*) mutation (Schonbaum *et al.*, 1995), and is referred to as the yolkless protein, Yl. Despite their unrelated ligands, the Yl shares high sequence identity with insect VgRs (Sappington *et al.*, 1996; Sappington and Raikhel, 2004), and polyclonal antibodies raised to *A. aegypti* VgR recognize the *D. melanogaster* Yl (Richard *et al.*, 2001) indicating similar tertiary structures.

Dantuma *et al.* (1999) cloned the *L. migratoria* Lp receptor (LpR) and determined that it is a member of the LDL receptor (LDLR) family. The locust LpR is expressed primarily in the fat body, but it is also present in the ovary. The cDNA for a similar lipoprotein receptor (LpR), which is likely responsible for the uptake of Lp by *A. aegypti* oocytes (Sun *et al.*, 2000), has been cloned by Cheon *et al.* (2001). Two splice variants of *LpR* mRNA have been identified that give rise to AaLpRfb and AaLpRov, which are specific for the fat body and the ovary, respectively (Seo *et al.*, 2003). In addition to recognizing Yl, anti-*Aedes* VgR polyclonal antibodies recognize an abundant 80 kDa protein in *D. melanogaster* ovaries, which possibly represents an ovarian LpR, in addition to Yl (Richard *et al.*, 2001). Genes encoding putative LpRs also have been identified in the *Drosophila* genome (Culi and Mann, 2003). Thus, two distinct receptors appear to exist for YPs and Lp in this species.

1.3.3.2.3.2. The superfamily of low-density lipoprotein receptors The insect VgRs, Yl, and LpRs are all members of the low-density lipoprotein receptor (LDLR) superfamily, named after the LDLR first described in humans (Yamamoto *et al.*, 1984). LDLR-superfamily members are characterized by various arrangements of five structural domains (**Figure 11**): (1) *class A complement-type imperfect repeats*, often referred to as ligand-binding repeats (LRs), each containing six cysteine residues that form an invariant pattern of disulfide bonds (Bieri *et al.*, 1995a, 1955b); (2) *class B EGF-type imperfect repeats*, also containing six cysteine residues, which, however, form a pattern of disulfide bonding different than that of the cysteines in the class A repeats (Campbell and Bork, 1993); (3) *YWXD imperfect repeats*, invariably occurring in groups of six, which fold to form a compact 6-bladed β-propeller structure (Springer, 1998; Jeon *et al.*, 2001) that is involved in acid dissociation of the receptor and its ligand in the endosome (Innerarity, 2002) – this domain is often considered part of a larger EGF precursor homology domain, which includes the class B repeats (Nimpf and Schneider, 1998; Hussain *et al.*, 1999); (4) a *single-pass transmembrane domain* near the C-terminus; and (5) a *cytoplasmic tail* that includes one or more tyrosine or dileucine-based internalization signals. In addition, there is often an extracellular *O*-linked sugar region proximal to the membrane, and in some cases, the presence or absence of this domain is determined by differential splicing (e.g., Bujo *et al.*, 1995). Besides the presence of these domains, Hussain *et al.* (1999) list other characteristics of LDLR-superfamily members, including cell-surface expression, a requirement of Ca^{2+} for ligand binding, and internalization of ligands by receptor-mediated endocytosis.

One of the most striking structural characteristics noticed when comparing LDLR-superfamily members, is the clustering of class A modules into 1–4 distinct ligand-binding domains, with a characteristic number of modules per domain (**Figure 11**). Complete VgR sequences are known from five species of vertebrates (Bujo *et al.*, 1994; Okabayashi *et al.*, 1996; Davail *et al.*, 1998; Li *et al.*, 2003; Hiramatsu *et al.*, 2004), and are characterized by a single ligand-binding domain containing eight class A modules. Similarly, the mosquito ovarian LpR (AaLRov) has eight class A modules in a single cluster (Cheon *et al.*, 2001). Alternatively, the fat body-specific LpR isoform (AaLpRfb) consists of seven complement-type, cysteine-rich repeats in its putative ligand-binding domain, which are identical to the second through eighth repeats of AaLpRov. The *AaLpRov* transcripts are present exclusively in ovarian germ-line cells, nurse cells, and oocytes, while the *AaLpRfb* transcripts are fat body-specific (Seo *et al.*, 2003). The differences between these two isoforms suggests that they internalize Lps with different apo-Lp compositions.

Finally, insect VgRs/Yl have two clusters of class A modules (**Figure 11**). The first cluster contains five modules in all except for the *S. invicta* VgR, which only has four. The second cluster contains

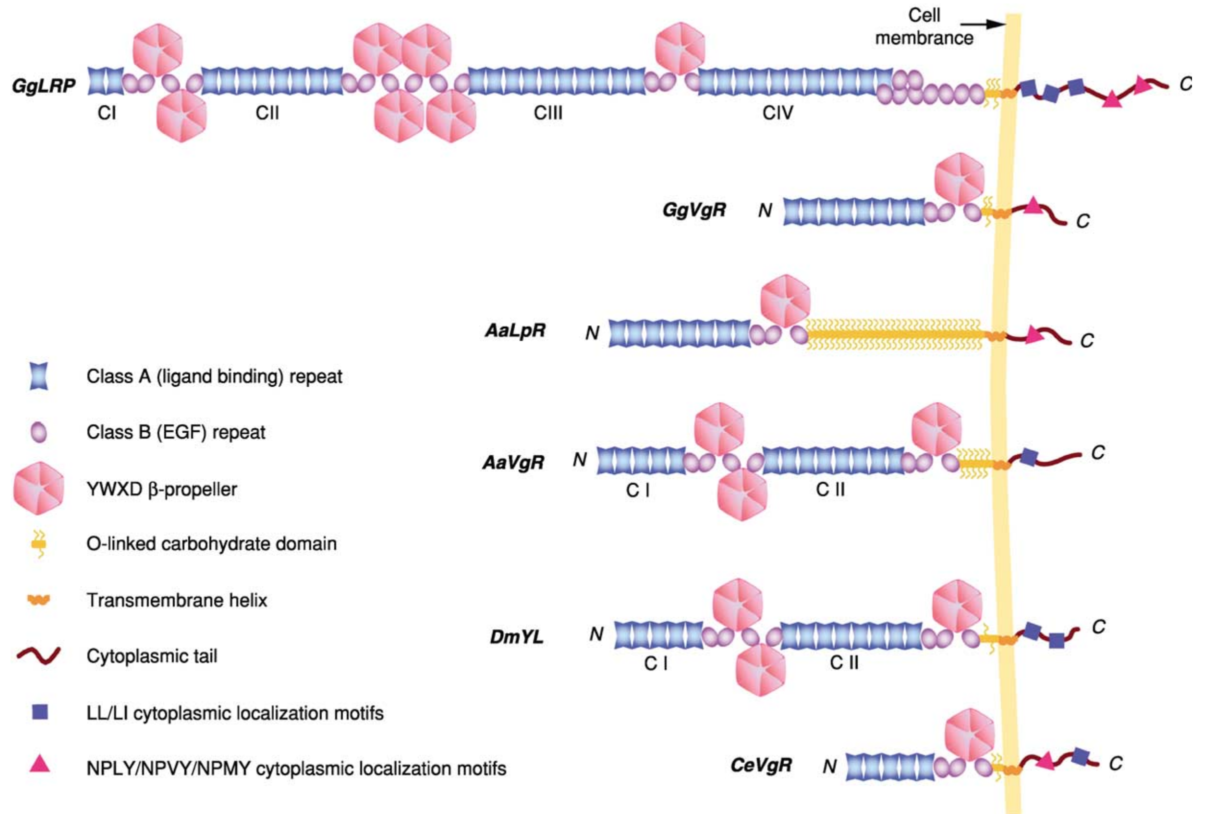

Figure 11 Schematic illustration of receptors of the LDLR superfamily, which are known to internalize yolk protein precursors into oocytes, emphasizing the arrangement of various modular domains. The C-terminus of each receptor is located on the cytoplasmic side of the cell membrane, while the N-terminus is extracellular. CI, first cluster of class A (ligand-binding) repeats in multi-cluster receptors; CII, second cluster, etc. The relative locations of tyrosine-based (NPXY) or dileucine-based (LL or LI) internalization signals in the cytoplasmic tail are also indicated. *GgLRP*, chicken (*Gallus gallus*) LDLR-related protein; *GgVgR*, chicken (*G. gallus*) vitellogenin receptor; *AaLPR*, mosquito (*Aedes aegypti*) lipophorin receptor; *AaVgR*, mosquito (*A. aegypti*) vitellogenin receptor; *DmYl*, fruit fly (*Drosophila melanogaster*) yolkless protein (or YP receptor); *CeVgR*, nematode (*Caenorhabditis elegans*) vitellogenin receptor. (Modified from Sappington, T.W., Raikhel, A.S., **2004**. Insect vitellogenin/yolk protein receptors. In: Raikhel, A.S., Sappington, T.W. (Eds.), Progress in Vitellogenesis, vol. XII, Part B. Science Publishers, Inc., Enfield, NH, pp. 229–264.)

either eight (*A. aegypti* VgR and *D. melanogaster* Yl) or seven repeats (*P. americana* and *A. gambiae* VgRs). A search of the *D. melanogaster* genome (Adams *et al*., 2000) revealed the presence of seven LDLR superfamily members (Culi and Mann, 2003), including homologs of the very large LDLR-Related Protein-2 receptors of vertebrates (Herz and Bock, 2002). The role of these large receptors in insects is unknown. For a more detailed analysis of insect RME receptors, the characteristics of their domains and their functional relevance, the reader is referred to a recent review by Sappington and Raikhel (2004).

1.3.3.2.4. Concluding remarks In addition to the physiological and functional importance of yolk accumulation in the oocyte to any reproducing insect, the processes and proteins involved are fundamental to many aspects of cell biology in animals in general. For example, RME of macromolecules is a ubiquitous process of eukaryotic cells (Goldstein *et al*., 1979; Schwartz, 1995). Insect Vgs are related to the Vgs of vertebrates and nematodes (Chen *et al*., 1997), and belong to a yet larger superfamily of proteins called large lipid transfer proteins (LLTP) (Babin *et al*., 1999). The apolipoprotein component of vertebrate LDL, a molecule involved in cholesterol homeostasis (Brown and Goldstein, 1986), is an LLTP (Byrne *et al*., 1989; Chen *et al*., 1997). Insect VgRs, Yl, and LpRs are related to vertebrate and nematode VgRs, and all belong to the larger LDLR superfamily, which bind a variety of ligands including LLTPs (Sappington and Raikhel, 1998a, 1998b, 2004; Babin *et al*., 1999). The YPs of *Drosophila* are related to lipoprotein lipases (Bownes *et al*., 1988b), a ligand of certain vertebrate LDLR superfamily receptors (Beisiegel, 1996). Thus, the evolutionary connections among these proteins in widely divergent animal taxa are pervasive. The importance of this cannot be overemphasized, because the commonalities in these systems

make studies on the mechanisms of insect yolk accumulation relevant to mechanisms of cholesterol homeostasis and LDLR-based genetic diseases in humans (Gliemann, 1998; Herz and Farese, 1999; Hussain *et al.*, 1999; Willnow, 1999; Nykjaer and Willnow, 2002; Strickland *et al.*, 2002), and *vice versa*. Thus, those working in these normally disjunct fields of research have much to offer and learn from one another (Sappington and Raikhel 1998b, 2004; Sappington *et al.*, 2002).

1.3.3.3. The Transition from Vitellogenesis to Choriogenesis

At the end of vitellogenesis, the cells of the follicular epithelium lose their patency, and this results in a cessation of yolk protein transport to the oocyte surface (Wang and Telfer, 1996). Concurrently, gene expression in the cells of the follicular epithelium switches from yolk protein gene transcription to the activation of eggshell or chorion protein-encoding genes (Kafatos *et al.*, 1977). Prior to choriogenesis, the nurse cells also empty their cytoplasmic contents into the oocyte and undergo apoptosis (Mahajan-Niklos and Cooley, 1994).

During the vitellogenic stages that precede the onset of choriogenesis, other important events occur in follicles, including the synthesis of vitelline membrane proteins and ovarian (maternal) ecdysteroids by the cells of the follicular epithelium (Kadono-Okuda *et al.*, 1994; Kendirgi *et al.*, 2002), the reinitiation of meiosis in the oocytes (Lanot *et al.*, 1990), and morphogenetic movements of the follicular epithelium prior to their commitment to chorion protein gene expression (Spradling, 1993; Montell, 2001).

1.3.3.3.1. Diptera As is the case for the transition from previtellogenesis to vitellogenesis, most of the information regarding the transition from vitellogenesis to choriogenesis comes from the two major insect models, the fruit fly *D. melanogaster*, and the mosquito *A. aegypti*.

***1.3.3.3.1.1.* Drosophila melanogaster** Particular elements of the process of transition from vitellogenesis to choriogenesis, such as the patterning and movements of the follicular epithelium and the nurse cell dumping process, have been analyzed in detail by genetic methods in *Drosophila*. These processes will be discussed briefly in Sections 1.3.3.6 and 1.3.3.7, respectively, and are also reviewed in more detail in **Chapter 1.2**.

No detailed *in vitro* culture experiments of *Drosophila* ovarian follicles have been carried out to determine whether the transition from vitellogenesis to choriogenesis occurs as a follicle-autonomous process or whether it requires the presence of extra-ovarian factors (see also discussion in Section 1.3.3.3.2.1). Detailed measurements of ecdysteroid levels with respect to follicle development have also not been carried out in order to deduce whether the transition to choriogenesis is accompanied by a decline of ecdysteroid production in the cells of the follicular epithelium (see also discussion for *A. aegypti* and *B. mori* in Sections 1.3.3.3.1.2 and 1.3.3.3.2.1, respectively). Furthermore, genetic analysis has yet to reveal the components of a "master" regulatory pathway that governs the transition from vitellogenesis to choriogenesis in *Drosophila*. Therefore, the mechanism by which the cells of the follicular epithelium differentiate from a patent state that is involved in the synthesis of yolk proteins and allows free passage of hemolymph yolk proteins to the oocyte surface, to one that becomes specialized for chorion protein production, remains unknown in *Drosophila*.

1.3.3.3.1.2.* Aedes aegypti *and anautogenous flies In *A. aegypti*, the transition from vitellogenesis to choriogenesis is accompanied by a decline in ecdysteroid levels (Hagedorn, 1985). A decline in the abundance of the mRNAs of nuclear receptors involved in the ecdysone regulatory pathway, i.e., *AaEcR*, *AaUSP*, *AaE74B*, *AaE75A/B/C*, *AHR3*, also occurs in the ovary at the time of termination of vitellogenesis (Cho *et al.*, 1995; Pierceall *et al.*, 1999; Kapitskaya *et al.*, 2000; Wang *et al.*, 2000; Sun *et al.*, 2002). Also, the levels of the nuclear receptor AaHNF4b are down-regulated at this transition (Kapitskaya *et al.*, 2000). By contrast, the levels of *AaE74A* mRNA increase at the end of vitellogenesis and during choriogenesis (Sun *et al.*, 2002). The changes in the expression levels of the above factors suggest their involvement in the regulation of the transition from vitellogenesis to choriogenesis. However, as has been discussed in Section 1.3.3.1.1.2, it is not clear whether the expression levels of the above nuclear receptors in ovarian tissue are under control of the ecdysone regulatory pathway.

In the mosquito, a peptide hormone involved in the termination of vitellogenesis, trypsin-modulating oostatic factor (TMOF), is produced during vitellogenesis by the cells of the follicular epithelium (Borovsky *et al.*, 1990, 1994b). The target of TMOF is the gut, where it inhibits biosynthesis of trypsin and stops the breakdown of blood proteins that are essential for vitellogenesis (Borovsky *et al.*, 1990, 1994a, 1994b) (see also **Chapters 1.5** and **3.9**). Thus, the action of TMOF blocks the availability of nutrients necessary for

continuation of vitellogenesis. Because TMOF is produced by the cells of the follicular epithelium, a model emerges, in which ovarian follicles produce TMOF upon reaching a certain size, in order to prevent further growth and initiate post-vitellogenic events (De Loof *et al.*, 1995).

A functional analog of TMOF (Neb-TMOF) has also been isolated from *Neobellieria* (*Sarcophaga*) *bullata*, a fly that requires a protein meal to initiate vitellogenesis (anautogenous flies; Huybrechts and De Loof, 1977). Neb-TMOF is produced by vitellogenic follicles but, in this case, the oocyte rather than the cells of the follicular epithelium is the major source of the peptide (Bylemans *et al.*, 1996). The effects of Neb-TMOF include inhibition of trypsin biosynthesis in the gut and concomitant lowering of yolk protein concentration in the hemolymph (Bylemans *et al.*, 1994). A second oostatic factor or folliculostatin of *Neobellieria*, Neb-colloostatin, however, does not inhibit the synthesis of trypsin-like molecules in the gut and does not terminate viellogenesis in vitellogenic follicles. Instead, the peptide prevents previtellogenic follicles from entering vitellogenesis, and may be involved in the feedback mechanism that blocks vitellogenic growth of the penultimate oocyte before completion of vitellogenesis in the terminal follicle (Bylemans *et al.*, 1995).

In the female blowfly, *Phormia regina*, ovarian ecdysteroidogenesis is regulated by antagonistic activities of cAMP (positive regulation) and cGMP (negative regulation) second messengers (Manière *et al.*, 2000, 2003). Calcium signaling is also involved, since calcium ions inhibit steroidogenesis, presumably by activating a calmodulin-sensitive (type I) phosphodiesterase (Manière *et al.*, 2002). Cyclic GMP levels in the blowfly ovary reach their maximal levels at the end of vitellogenesis, in close association with a decrease in ecdysteroidogenesis. Thus, cGMP may signal the end of vitellogenesis through inhibition of ovarian ecdysone production and concomitant inhibition of ecdysone-regulated yolk protein production. The regulation of cGMP levels does not seem to be dependent on extra-follicular factors but may involve paracrine or autocrine factors, possibly nitric oxide (Manière *et al.*, 2003).

1.3.3.3.2. Lepidoptera Information regarding the regulation of the transition from vitellogenesis to choriogenesis in lepidopteran insects has been derived almost exclusively from one species, the domesticated silkmoth, *B. mori*.

***1.3.3.3.2.1.* Bombyx mori** The developing ovariole of the silkmoth, *B. mori*, represents an excellent system for the study of changes in gene expression during follicle development (Swevers and Iatrou, 2003). Because of the asynchronous nature of oogenesis (**Figure 12**), follicles at all different stages of development are simultaneously present and arranged in a linear array in each of the animal's 8 ovarioles (Bock *et al.*, 1986; Swevers and Iatrou, 1992), with each follicle differing from its immediate neighbor by 2–2.5 h of developmental distance. This feature allows the isolation of all stages of oogenesis by dissection of a single female pharate adult.

Because the transition between vitellogenic and choriogenic follicles is easily visible by eye, a

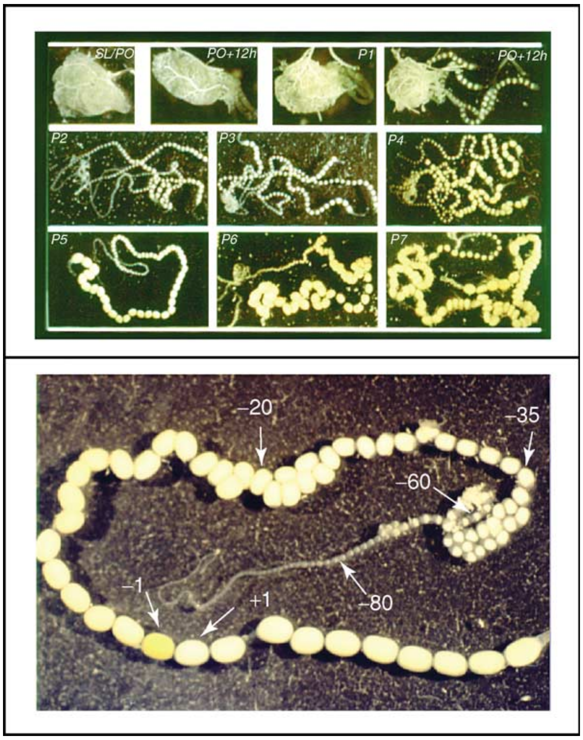

Figure 12 Structure of the developing ovary of the silkmoth, *Bombyx mori* at different stages of development. Upper panel: Development of the ovary of the silkmoth, *B. mori*, in spinning larvae, pupae and pharate adults. In spinning larvae (SL) and pupae until 12 h after larval–pupal ecdysis (P0 and P0 + 12 h), the ovarioles are still enclosed within a protective capsule. When ecdysteroid titers rise in the hemolymph, the capsule ruptures and the ovarioles emerge in the abdominal cavity (P1, P1 + 12 h). Two to three days after ecdysis, vitellogenesis is initiated (P2 and P3) while choriogenesis starts 5 days after ecdysis (P5). During the second half of pharate adult development, choriogenic follicles accumulate in the ovarioles and ovulation ensues (P7). SL, spinning larvae; Pn (+12 h), pupae or pharate adults, n days (+12 h) after larval pupal ecdysis. Lower panel: Structure of a silkmoth ovariole, 6–7 days after larval–pupal ecdysis. Indicated are the various stages of vitellogenesis (−1 to −nn) and choriogenesis (+1 to +nn). In this numbering system, vitellogenesis is initiated at −60, while choriogenesis starts at +1. (Lower panel: Reprinted with permission from Swevers, L., Iatrou, K., **2003**. The ecdysone regulatory cascade and ovarian development is lepidopteran insects: insights from the silkmoth paradigm. *Insect Biochem. Mol. Biol.* 33, 1285–1297; © Elsevier.)

numbering system has been devised to stage the development of follicles (Kafatos *et al.*, 1977). In this numbering system, the first choriogenic follicle acquires the number +1 and successive later stages of choriogenic development (differing by 2.5 h of developmental distance) are given correspondingly higher positive numbers; vitellogenic follicles, alternatively, are numbered with negative numbers, with follicle −1 representing the last stage of vitellogenesis (**Figure 12**).

The developing ovariole is especially suitable for the study of program of follicular cell differentiation from middle vitellogenesis to choriogenesis (stages −30 to −35 and later), because at these stages individual follicles have reached a size sufficiently large to allow easy manipulation for physiological, biochemical, and gene expression studies. Thus, Northern blot analysis has been used to elucidate the changes in the expression patterns of transcription factors during the transition from vitellogenesis to choriogenesis, and correlate such expression patterns with those of structural genes, e.g., genes encoding yolk, vitelline membrane, and chorion proteins (Swevers and Iatrou, 1999, 2003). In many cases, the expression analysis of the mRNA has been coupled with the detection of the corresponding proteins in the follicles by Western blot analysis and immunocytochemistry.

1.3.3.3.2.1.1. In vitro *culture experiments* Mid to late vitellogenic follicles (stages from approximately −35 onwards) are capable of developing in organ culture in a chemically defined medium, completing vitellogenesis and, also, entering and completing the choriogenic program autonomously (Swevers and Iatrou, 1992). Previously, it was also shown that the program of chorion gene expression in the American silkmoth, *Antheraea polyphemus* is also follicle-autonomous (Paul and Kafatos, 1975)

However, it was also observed in *Bombyx* that only a limited number of middle vitellogenic follicles (stages −30/−35 and later) have the capacity to develop autonomously *in vitro* (Swevers and Iatrou, 1992). This finding suggested that follicles of earlier vitellogenic stages require the presence of an extraovarian (hemolymph) factor(s), which triggers the activation of a regulatory cascade allowing the follicles to complete vitellogenesis, and enter and complete choriogenesis autonomously. According to the proposed model, follicles at stages −35/−30 and beyond (at the time of dissection), have acquired the competence to respond to a circulating signal (e.g., a hormone present in the hemolymph) that allows them to develop further autonomously. The term competence implied the stage-specific appearance in the follicles (probably the cells of the follicular epithelium) of a receptor that allows the binding of the circulating signal and the triggering of a relevant regulatory cascade, which establishes the autonomy of the differentiation program. Thus, follicles lacking this capacity (at stages earlier than −35) are unable to respond to the putative signal and cannot proceed autonomously through the execution of the autonomous part of the differentiation program (Swevers and Iatrou, 1992).

To elucidate the nature of the postulated extraovarian factor(s), two approaches have been considered useful: (1) to culture ovarioles in the presence of hemolymph (and, eventually, purified hemolymph factors) or known hormones, and compare the developmental potential of follicles in supplemented versus nonsupplemented culture media; and (2) to search for genes encoding putative receptors and expressed in follicular cells at or around stages −30/−35 but not at earlier stages, because genes implicated in the transduction of the “autonomy signal” would be expected to be differentially expressed during these stages.

Following upon these two approaches, it has been demonstrated that the hormone 20E does not play a role in the induction of the choriogenic program in the follicular cells at mid vitellogenesis. Thus, addition of 20E to ovariole cultures did not change the capacity of vitellogenic follicles to develop autonomously toward subsequent stages (Swevers and Iatrou, 1992). Furthermore, it was determined that the components of the ecdysone receptor heterodimer, BmEcR and BmUSP, as well as the known downstream signaling components in the ecdysone regulatory pathway, are not expressed differentially in the cells of the follicular epithelium with respect to the stages of establishment of follicle autonomy (**Figure 13**) (Swevers *et al.*, 1995; Swevers and Iatrou, 2003).

Subsequent studies to address the issue of the establishment of developmental autonomy in the ovarian follicles have focused on bombyxins, a class of insulin-like peptides that have been isolated from *B. mori* brain extracts based on their prothoracicotropic activity (capacity to activate the prothoracic glands) in the moth *Samia cynthia ricini* (Nagasawa *et al.*, 1984; Jhoti *et al.*, 1987). The functions of bombyxins in *Bombyx* relate to the regulation of glucose metabolism and growth control (Satake *et al.*, 1997; Masumura *et al.*, 2000). High titers of bombyxins are also found in the hemolymph of female pharate adults suggesting an (as yet undefined) role in the regulation of female reproduction, possibly ovarian development (Saegusa *et al.*, 1992). Bombyxin-binding activity is detected in ovarian follicle membrane extracts,

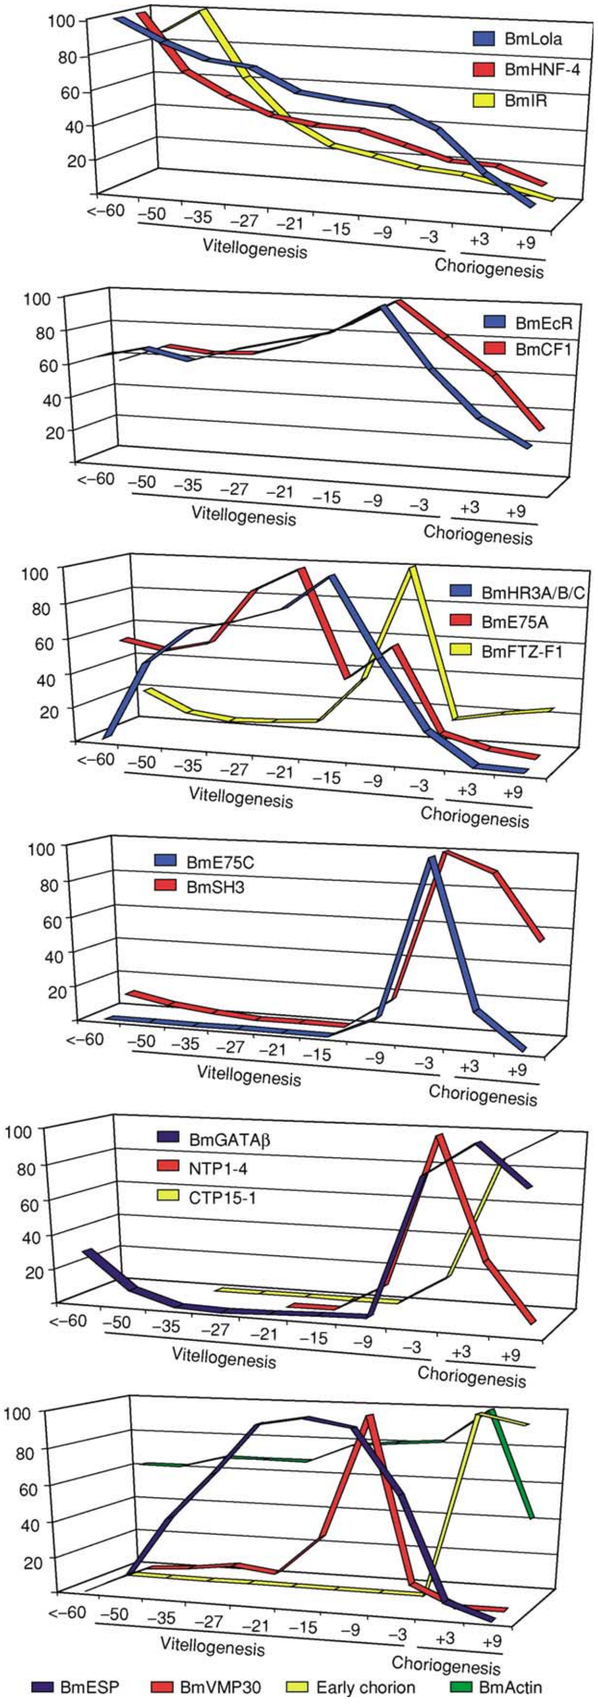

Figure 13 Schematic overview of the expression of the mRNAs of regulatory factors during follicular development in *Bombyx mori* as detected by Northern blot and quantified by Phosphorimager analysis. Expression levels for each gene are plotted relative to the highest signal (100%). Genes were grouped to show similarity in expression levels (first, second, fourth, and fifth panels), to illustrate cross-regulation (third panel) or to indicate broad developmental periods (structural genes in sixth panel). First panel: Genes whose expression levels decline gradually as oogenesis progresses: BmHNF-4, BmIRL, and BmLola. BmLola is the homolog of the *Drosophila* transcription factor Lola that is characterized by an N-terminal BTB-domain and C-terminal C_2H_2 zinc fingers (Giniger *et al.*, 1994). Second panel: Expression of the mRNAs of the components of the ecdysone receptor heterodimer, BmEcR and BmUSP. Both mRNAs are present at similar levels throughout most of vitellogenesis, peak at the end of vitellogenesis, and decline during choriogenesis. Third panel: Expression of the nuclear receptors BmHR3A, BmE75A, and BmFTZ-F1. Note that BmFTZ-F1 becomes induced at maximal values of BmHR3A, concomitantly with a drop in expression levels of BmE75A. Fourth panel: Induction of the mRNAs of the nuclear receptor BmE75C and the adaptor protein BmSH3 at the end of vitellogenesis. The two factors interact in yeast two-hybrid assays and may form a functional complex in the follicular cells. Fifth panel: Induction of the mRNAs of BmGATAβ and two putative interacting factors (NTP 1–4 and CTP 15–1; Glushek, 2001) in the follicular epithelium at the end of vitellogenesis. Sixth panel: Expression of structural genes and developmental markers. ESP is the yolk protein produced by the follicular cells and is a marker of vitellogenesis, BmVMP30 is a vitelline membrane protein expressed during mid-late vitellogenesis, and early chorion genes are induced at the beginning of choriogenesis. BmActin corresponds to the cytoplasmic actin gene; note that its expression shows a peak at the beginning of choriogenesis followed by a sharp decline. Numbers at the bottom of each graph indicate the stages of oogenesis with respect to the start of choriogenesis (+1). The expression levels that are indicated are obtained from pools of 6 follicles (+9, +3, −3, −9, −15, −21, −27), 10 follicles (−35), 20 follicles (−50), or represent the remainder of follicles earlier than −60 (<−60). The numbers indicate the follicle that is the midpoint of each series of 6 follicles (for instance, +9 = +7/+12), 10 follicles (−35 = −31/−40), or 20 follicles (−50 = −41/−60). ''<−60'' represents a large number (> 50) of early follicles. The broad developmental periods of vitellogenesis and choriogenesis are also indicated. (Reprinted with permission from Swevers, L., Iatrou, K., **2003**. The ecdysone regulatory cascade and ovarian development in lepidopteran insects: insights from the silkmoth paradigm. *Insect Biochem. Mol. Biol. 33*, 1285–1297; © Elsevier.)

indicating that ovarian tissue is a direct target tissue of bombyxin peptides (Fullbright *et al*., 1997). Furthermore, the expression of bombyxin mRNAs in ovarian tissue (Iwami *et al*., 1996) also indicates a possible autocrine or paracrine role for bombyxins during follicle development. A gene encoding a putative receptor for bombyxins, the *Bombyx* insulin receptor-like (BmIRL) protein, was cloned (**Figure 14**; I. Lindström-Dinnètz and K.I., unpublished data), and the expression pattern of its mRNA during follicle development determined (Swevers

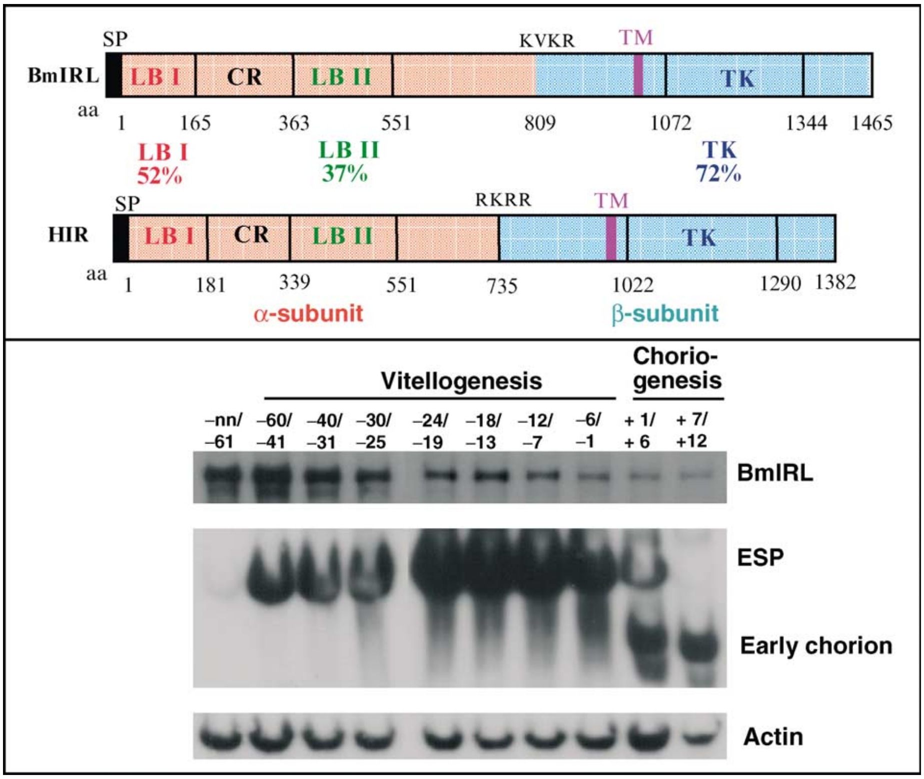

Figure 14 Structure and expression pattern of the *Bombyx* insulin-like receptor (BmIRL; GenBank accession number AF025542). Upper panel: Schematic drawing of the BmIRL protein and comparison with the human insulin receptor (HIR). Indicated are the signal peptide (SP), the ligand-binding domains I and II (LB I and II), the cysteine-rich region (CR) of the α-subunit, the documented cleavage site (RKRR) for processing of HIR into α- and β-subunits, the transmembrane region (TM), and the tyrosine kinase (TK) domain of the β-subunit. Note that the proteolytic processing at the putative cleavage site (KVKR) of BmIRL has yet to be demonstrated. Percentages indicate % identity of selected domains with the corresponding domains of the human insulin receptor. Lower panel: Expression of *BmIRL* mRNA during follicle development. Expression of *Esp* and early chorion mRNA indicates the developmental period of vitellogenesis and early choriogenesis, respectively, and actin hybridizations are shown as control for the integrity of the RNA samples. Molecular weight sizes are 12 kb (BmIRL), 2 kb (ESP), 0.6 and 0.4 kb (early chorion), and 1.3 kb (actin). (Lower panel: Reprinted with permission from Swevers, L., Iatrou, K., **2003**. The ecdysone regulatory cascade and ovarian development in lepidopteran insects: insights from the silkmoth paradigm. *Insect Biochem. Mol. Biol. 33*, 1285–1297; © Elsevier.)

and Iatrou, 2003). The mRNA expression data, however, did not support the prediction for a role for BmIRL in the establishment of the autonomous portion of the program of differentiation at mid-vitellogenesis, as no differential expression was observed with respect to the stages, at which the autonomous capacity is induced in the follicular epithelium (Swevers and Iatrou, 2003). Because the *BmIRL* gene is mainly expressed in previtellogenic and early vitellogenic follicles (**Figures 13 and 14**), signaling through BmIRL is predicted to contribute to the early growth of ovarian follicles. The caveat for this conclusion, however, is that work for the detection of the receptor protein itself through Western analysis or immunolocalization, has not been carried out. Subsequent binding studies, to demonstrate that BmIRL is indeed the receptor for bombyxins, have also been inconclusive (E. Bullesbach, L.S., and K.I., unpublished data). Thus, the question of whether bombyxins are the sought-after inducing signal that establishes autonomy in follicular cells, remains unanswered.

1.3.3.3.2.1.2. Requirement for a decline in 20E signaling In *B. mori*, the transition from vitellogenesis to choriogenesis occurs during those stages of pharate adult development, when the hemolymph titers of ecdysteroids have already declined to low, nearly undetectable levels (Tsuchida *et al*., 1987). Thus, it can be anticipated that the transition from vitellogenesis to choriogenesis is triggered by a decline in the primary 20E signaling in the developing vitellogenic follicles.

Experiments using the nonsteroidal ecdysone agonist tebufenozide have indeed shown that continuous signaling of the 20E pathway blocks ovarian development at mid to late vitellogenesis (Swevers and Iatrou, 1999). Because tebufenozide activates

the 20E signaling pathway at lower concentrations than 20E and persists in tissues much longer than the naturally occurring hormone, it causes prolonged 20E signaling that results in developmental arrest (Retnakaran *et al*., 1995).

When tebufenozide was injected in *Bombyx* developmentally arrested abdomens, ovarian development was induced and the follicles entered the developmental program of vitellogenesis with similar kinetics as in 20E-injected abdomens (Swevers and Iatrou, 1999). However, the transition from vitellogenesis to choriogenesis, monitored through the activation of chorion protein-encoding genes, an event associated with a decline in ecdysteroid titer, did not occur in tebufenozide-injected abdomens (see **Figure 4**). Thus, the experiments with tebufenozide have demonstrated unequivocally that vitellogenic follicles require a decline in 20E-signaling in order to progress towards choriogenesis.

1.3.3.3.2.1.3. Expression patterns of regulatory factors Comparison of the patterns of expression of regulatory factors between normally developing follicles obtained from intact animals and those of arrested follicles obtained from tebufenozide-injected abdomens has led to the identification of a regulatory cascade that is induced in follicular epithelium cells by the declining 20E titers and controls the transition from vitellogenesis to choriogenesis (Swevers and Iatrou, 1999).

At the top of the regulatory cascade stands the orphan nuclear receptor BmFTZ-F1 (Sun *et al*., 1994), which becomes expressed in the follicles at vitellogenic stages −18 to −7 (**Figure 13**). In *Drosophila*, βFTZ-F1 was shown to act as a competence factor during periods of low ecdysteroid signaling; between the periods of high ecdysteroid titers, tissues require low ecdysteroid titers and/or expression of FTZ-F1 in order to regain their capacity to respond properly to a consecutive pulse of 20E (Woodard *et al*., 1994; Broadus *et al*., 1999). Because BmFTZ-F1 seems to be the first factor induced by the declining ecdysone titers in *Bombyx* follicles, it may also function as a competence factor to control the transition from vitellogenesis to choriogenesis.

Interestingly, the induction of BmFTZ-F1 during vitellogenesis coincides with the highest expression levels of BmHR3A as well as with a drop in the expression levels of BmE75A (**Figure 13**; Swevers and Iatrou, 1999; Eystathioy *et al*., 2001; Swevers *et al*., 2002a). Moreover, in transient expression experiments employing *Bombyx*-derived tissue culture cells, BmHR3A and BmE75A function as activators and repressors, respectively, of reporter genes that harbor retinoic acid receptor-related orphan receptor elements (ROREs; binding elements for the HR3 and E75 orphan nuclear receptors) in their upstream regions (**Figure 15**; Swevers *et al*., 2002b). Because of the antagonistic activities displayed by BmHR3A and BmE75A, it was proposed that activation of RORE-dependent target genes depends on the relative expression levels of BmHR3A and BmE75A. It could indeed be demonstrated that during *Drosophila* metamorphosis, prolonged expression of E75 can prevent the activation of the *βFTZ-F1* gene by HR3 (White *et al*., 1997; Kageyama *et al*., 1997; Lam *et al*., 1997). The action of *Drosophila* HR3 and E75 is mediated through their interaction with RORE sites in the *βFTZ-F1* promoter. Whether similar sites also exist in the *Bombyx BmFTZ-F1* promoter is unknown at present, but it is tempting to speculate that the relative levels of BmHR3A and BmE75A determine the induction of BmFTZ-F1 during middle vitellogenesis in *Bombyx* follicles, according to a similar mechanism as that observed during metamorphosis in *Drosophila*.

The induction of BmFTZ-F1 is followed by changes in the expression of several other regulatory factors (**Figure 13**). Thus, at stages −12/−7, induction of the genes encoding the orphan nuclear receptor BmE75C and the adaptor protein BmSH3 occurs, while a concomitant strong decline is observed in the expression of the BmHR3 receptors (all isoforms). Furthermore, a strong decline in the levels of BmFTZ-F1 mRNA is observed at stages −6/−1, while the gene encoding the transcriptional regulator BmGATAβ becomes strongly upregulated at the same time (Drevet *et al*., 1995; Swevers and Iatrou, 1999; Eystathioy *et al*., 2001; Swevers *et al*., 2002a).

For most of the factors described above, however, their exact function in the program of follicular cell differentiation is unknown at present. *BmE75C* is initially induced in ovaries as an early response gene at the beginning of pupation but its expression is not sustained, and the transcription of this mRNA is rapidly downregulated (Swevers *et al*., 2002a). The subsequent (ecdysteroid-independent) increase in the expression of *BmE75C* mRNA (and protein) at stages −12 to +12 is consistent with a function as a regulator of the transition from vitellogenesis to choriogenesis. Because BmE75C acts as a transcriptional repressor in tissue culture cells (**Figure 15**; Swevers *et al*., 2002b), its function in follicular cells may be related to the shut-down of the vitellogenic program rather than the onset of choriogenesis.

BmSH3, a member of a family of conserved adaptor proteins characterized by three SH3 domains at the C-terminus and a lipid raft-targeting “SoHo” domain located at the N-terminus, was isolated

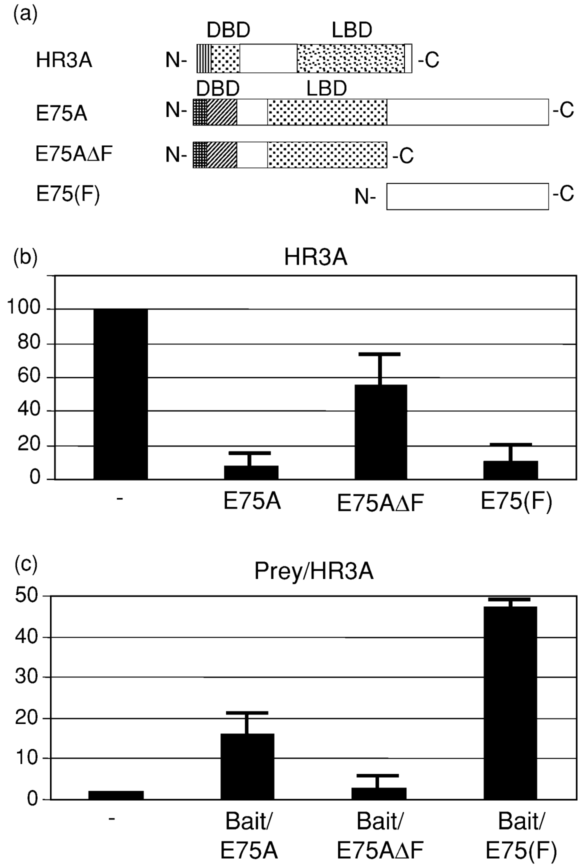

Figure 15 Functional interaction between the nuclear receptors BmHR3A and BmE75A. Panel (a): Schematic drawing of the nuclear receptors BmHR3A, BmE75A, and deletion mutants of BmE75A. In BmE75AΔF the C-terminal F-domain is deleted from the full-length receptor while BmE75(F) only consists of the F-domain. The two conserved domains of nuclear receptors, the DNA-binding domain (DBD) and ligand-binding domain (LBD) are indicated. Panel (b): BmE75A represses RORE-dependent reporter gene activation by BmHR3A in a silkmoth-derived cell line. Cells were transfected with RORE-dependent reporter plasmid and expression plasmids of *BmHR3A, BmE75A* and deletion mutants of *BmE75A*. ''–'': Transactivation by BmHR3A only; ''BmE75A'': Transactivation in the presence of BmHR3A and BmE75A; ''BmE75AΔF'': Transactivation in the presence of BmHR3A and BmE75AΔF; ''BmE75(F)'': Transactivation in the presence of BmHR3A and BmE75(F). Values of reporter gene activity are expressed as % of the activity obtained in the presence of BmHR3A only (''–'' column). Note that the F-domain of BmE75 is capable to repress transactivation by BmHR3A, due to interactions with the C-terminal activation function of BmHR3A (Swevers *et al.*, 2002b). Panel (c): Interactions between BmE75A and BmHR3A in yeast two-hybrid assays. Fusions between *BmE75A* or its deletion mutants and the DNA-binding domain of *Gal4* (''Bait'' proteins) were tested for interaction with a fusion between *BmHR3A* and the activation domain of *Gal4* (''Prey'' protein). In ''–,'' the empty ''bait'' vector was tested for interaction with Prey/HR3A. Relative reporter gene activities are expressed as percentages of the activity observed for the control interaction between p53 and SV40 large T-antigen. Note that the interaction between BmE75A and BmHR3A occurs via the F-domain of BmE75A; other experiments have shown that the F-domain forms a complex with the C-terminal activation domain of BmHR3A (data not shown; Swevers *et al.*, 2002b).

in a yeast two-hybrid screen using as bait the proline-rich N-terminus of BmE75C (K. Ito, L. Swevers, and K. Iatrou, unpublished data). Mammalian homologs of BmSH3 are involved in the transduction of tyrosine kinase signaling and the regulation of actin cytoskeleton organization (Baumann *et al.*, 2000; Kioka *et al.*, 2002). Thus, based on its structural features, BmSH3 may be involved in the regulation of the changes in the actin cytoskeleton in the cells of the follicular epithelium at the transition from vitellogenesis to choriogenesis (e.g., loss of patency, assembly of the chorion secretory machinery).

Finally, the BmGATAβ transcription factor has been hypothesized to be a major regulator of choriogenesis (Skeiky and Iatrou, 1991; Skeiky *et al.*, 1994; Drevet *et al.*, 1994, 1995) (see Section 1.3.4). Regarding a possible mechanism for the regulation of *BmGATAβ* gene expression, it should be noted that RORE binding sites exist in its promoter, which are bound by the BmHR3A orphan nuclear receptor in gel retardation assays. Because BmGATAβ and BmHR3A show reciprocal expression patterns during follicle development, it has been suggested that BmHR3A could act as a repressor of BmGATAβ expression (Eystathioy *et al.*, 2001). Although BmHR3A is known to act as a constitutive activator, as was mentioned earlier, its activation function can be repressed by the co-expression of BmE75A (Swevers *et al.*, 2002b). Thus, a possible mechanism for the silencing of the *BmGATAβ* gene during vitellogenesis may involve the recruitment of BmHR3A/BmE75A complexes to the RORE sites in the *BmGATAβ* promoter.

1.3.3.3.3. Other insects In insects, in which vitellogenin uptake by ovarian follicles is regulated by JH, termination of vitellogenesis can, in principle, be accomplished by two mechanisms: first, by a decrease in JH production by the CA or, second, by an increase in JH degradation in the hemolymph.

In the cockroach, *Diploptera punctata*, termination of vitellogenesis can be associated with a decline in JH titer (Sutherland *et al.*, 1998). Ovarian follicles that are in different stages of oogenesis exert different effects on the activity of the CA. Thus, follicles in active vitellogenesis stimulate JH production, while those near maturity inhibit it (Sutherland *et al.*, 2000). During the progression of vitellogenesis, the target for the ovarian inhibitory hormonal factor in the cells of the CA is proposed to be the CYP4C7 cytochrome P450 enzyme, which metabolizes JH and JH precursors by β-hydroxylation (Sutherland *et al.*, 1998, 2000). Thus, the decline in JH titer that is necessary to initiate post-vitellogenic events in

Diploptera, is mediated through a feedback signal from the ovary to the CA, which represses JH synthesis. By contrast, mechanisms that involve JH degradation by esterases in the hemolymph are thought to play a more minor role in the termination of vitellogenesis in this species.

In other cockroaches such as *L. maderae*, control of vitellogenesis is thought to be dependent on the fluctuation of the JH titer through the interplay among JH-binding proteins and JH degrading enzymes (for a relevant discussion, see Engelmann and Mala, 2000).

1.3.3.4. Ecdysteroidogenesis and Resumption of Meiosis

During the progression of vitellogenesis, ecdysteroid synthesis occurs in the cells of the follicular epithelium (Lagueux *et al*., 1977). However, in lepidopteran and orthopteran insects, most of the ecdysteroids produced by the follicular epithelium are inactive conjugates of ecdysone precursors and metabolites, and only very small amounts of active 20E are detected (Mizuno *et al*., 1981; Tawfik *et al*., 1999). In these insects, the ecdysteroids are not secreted to the hemolymph but are transported to the developing oocyte, where they are presumably stored as "maternal ecdysteroids" for use during embryonic development (Lagueux *et al*., 1981; Mizuno *et al*., 1981).

In the orthopteran *L. migratoria*, *in vitro* experiments have also shown that ecdysone promotes the reinitiation of meiosis in the oocyte at the end of vitellogenesis (Lanot *et al*., 1988, 1990). During oocyte growth, the oocyte nucleus (germinal vesicle) is arrested at the prophase of the first meiotic division. At middle to late vitellogenesis, however, germinal vesicle breakdown (GVBD) is initiated by the action of ecdysone produced by the follicular cells. Ecdysone is proposed to act at the level of the oocyte membrane, where it stimulates the production of cAMP (Lanot *et al*., 1988, 1990). After GVBD, the mature egg arrests again and remains arrested, until fertilization or some other signal triggers meiotic completion and further development.

In *B. mori*, ovarian ecdysteroid synthesis is initiated during day 4 of adult development (Ohnishi and Chatani, 1977), corresponding to the mid to late vitellogenic stages −20 to −25. Experiments using the ecdysteroid synthesis inhibitor KK-42 have shown that decreased ovarian ecdysteroid production does not affect ovarian growth, while it has profound effects on fertilization, embryogenesis, and larval hatching (Kadono-Okuda *et al*., 1994). These results suggest that, as is the case with *Locusta*, ovarian ecdysteroids are involved in the promotion of meiotic maturation in *Bombyx*. By contrast, since the experiments using the ecdysone agonist tebufenozide have shown that termination of vitellogenesis and initiation of choriogenesis requires a decline in 20E signaling (Swevers and Iatrou, 2003; Section 1.3.3.3.2.1.2), it is clear that the ecdysteroids produced by the follicular epithelium are not involved in the (autocrine or paracrine) regulation of follicle growth.

Interestingly, ecdysteroid synthesis in silkmoth follicles coincides with the expression of the nuclear receptor BmFTZ-F1, which also becomes expressed in follicular cells around stage −20 (**Figure 13**) (Swevers and Iatrou, 2003). BmFTZ-F1 is the insect homolog of the vertebrate nuclear receptor steroidogenic factor 1 (SF-1), which has essential roles in the differentiation of steroidogenic organs (gonads and adrenals) in vertebrates (Val *et al*., 2003). The SF-1 protein was originally isolated by its capacity to interact with and activate the promoters of steroidogenic enzymes (Rice *et al*., 1991; Morohashi *et al*., 1992). To deduce whether BmFTZ-F1 has a similar role in the regulation of ecdysteroidogenesis in ovarian tissue of *Bombyx*, the isolation of the genes encoding ecdysteroidogenic enzymes and the characterization of their promoter elements will be required.

In contrast to orthopteran and lepidopteran insects, the vitellogenic ovaries of dipteran insects (*Drosophila* and *Aedes*) synthesize significant amounts of 20E that are secreted into the circulation to stimulate vitellogenin synthesis in the fat body (Bownes, 1986; Raikhel *et al*., 1999; see also **Chapters 1.2**, **1.5**, and **3.9**). In *Drosophila*, the site of synthesis is the cells of the follicular epithelium, as demonstrated by the detection of the mRNA of the ecdysteroidogenic enzyme encoded by the *disembodied* (*dis*) gene through *in situ* hybridization (Warren *et al*., 2002) (see **Chapter 1.2**). In *Aedes* and *Phormia*, the synthesis of 20E is stimulated by neurohormones (see Sections 1.3.3.1.1.2 and 1.3.3.3.1.2), presumably through a cAMP-dependent mechanism (Brown *et al*., 1998; Manière *et al*., 2002). It has also been proposed that 20E stimulates ovarian growth by an autocrine/paracrine mechanism, although the evidence for this is not entirely convincing (Buszczak *et al*., 1999; see Section 1.3.3.1.1.1.3). However, whether ecdysteroids produced by the ovary of dipteran insects are also involved in the regulation of reinitiation of meiosis is not known. In *Drosophila*, as in *Locusta*, ovarian oocytes are arrested in prophase I during vitellogenic growth and undergo GVBD upon maturation (Page and Orr-Weaver, 1997; Chen *et al*., 2000) (see **Chapter 1.2**). The mature oocytes become arrested in metaphase I, but are released from the arrest when the eggs pass through the oviduct into the uterus (Heifetz *et al*., 2001) (see also Section

1.3.5). Thus, it can be hypothesized that the ecdysteroids produced by the follicular epithelium in *Drosophila* are also involved in the stimulation of the transition from prophase I to metaphase I during oocyte maturation.

1.3.3.5. Osmotic Swelling and Loss of Patency

The mechanism that triggers the loss of patency at the end of vitellogenesis has been studied mostly and is best understood in the lepidopteran *H. cecropia* (Telfer and Woodruff, 2002). In this species, loss of patency occurs through osmotic swelling (50% increase in cellular volume) of the cells of the follicular epithelium and concomitant closure of the intercellular spaces among the epithelial cells. This process is triggered by a rise in the cAMP content of the follicular cells (Wang and Telfer, 1996), which results in the activation of protein kinase A, and changes in the electrophysiological properties of the cells (increase of chloride ion conductance and potassium ion uptake, acidification of the cytoplasm, hyperpolarization) that result in fluid uptake (Wang and Telfer, 1998a). Interestingly, the rise in cAMP levels and loss of patency can also be effected by pertussis toxin, an inhibitor of the α subunit of inhibitory G proteins (Giα) (Wang and Telfer, 1998b). Thus, based on the assumption that Giα is a component of a conventional heterotrimeric G protein, it has been suggested that during vitellogenesis, cAMP levels in the epithelium remain low through signaling by an unknown GPCR that couples with Giα-containing G protein complexes. At the end of vitellogenesis, however, a decrease in signaling (loss of ligand or decrease in ligand sensitivity) through the hypothetical GPCR is postulated to lead to increased levels of cAMP, which result in osmotic swelling and loss of patency in the follicular epithelium (Wang and Telfer, 1998b). The transformation of the follicular epithelium, however, is thought not to be triggered by extrafollicular factors circulating in the hemolymph but by developmental changes occurring spontaneously in each follicle as it reaches a length of 2 mm (Wang and Telfer, 1996, 1998b).

The activation of protein kinase A in homogenates of follicles also results in the phosphorylation of a 32 kDa protein that has been speculated to represent ribosomal protein S6 (Wang and Telfer, 1996, 2000). However, cell-permeable cAMP analogs that inhibit phosphorylation of the 32 kDa protein, were found to be capable of triggering termination of vitellogenesis in intact follicles, suggesting that the phosphorylation of this protein is not involved in the pathway that terminates vitellogenesis.

Because the cells of the follicular epithelium and the oocyte communicate through gap junctions that allow exchange of ions and small solutes (Telfer and Woodruff, 2002), osmotic swelling occurs both in the cells of the follicular epithelium and the oocyte. However, the process seems to be triggered in the follicular cells because of their high levels of protein kinase A. Osmotic swelling occurs immediately (within 30 min after the rise in cAMP) in the follicular cells, while a significant delay exists for the oocyte. The delay in the swelling of the oocyte probably contributes to the requirement for a mechanical loosening of the vitelline envelope (see Section 1.3.3.8 below), which would otherwise prevent the immediate expansion of the oocyte volume (Wang and Telfer, 1998a).

1.3.3.6. Patterning and Movements of the Follicular Epithelium

The patterning and morphogenetic movements of the follicular epithelium at the transition from vitellogenesis to choriogenesis in *D. melanogaster* have been subject to several excellent recent reviews (Ray and Schüpbach, 1996; Van Eeden and St. Johnston, 1999; Dobens and Raftery, 2000; Riechmann and Ephrussi, 2001; Rørth, 2002) (see **Chapter 1.2**). Only a brief outline will be presented here. However, very little to no information on these important processes exists for other insects.

At the beginning of *Drosophila* vitellogenesis (stage 9), the follicular epithelium is organized in three domains: (1) a small cluster of border cells that has delaminated from the anterior pole of the follicle and migrates between the cells of the nurse cell complex towards the oocyte surface, (2) a squamous epithelium that covers the nurse cell cluster, and (3) a columnar epithelium that covers the oocyte. At the end of vitellogenesis (stage 10B), the nurse cells start dumping their contents into the oocyte (see below), while the most anterior cells of the columnar epithelium move centripetally between the nurse cell cluster and the oocyte to seal the anterior surface of the oocyte. The centripetally migrating cells stop their migration when they meet the border cells. The leading cells of the centripetally moving population of follicular epithelium cells, together with the border cells, form the micropyle of the eggshell, while the remainder of the centripetally moving cells build the operculum. During stage 11, the main body follicle cells also stretch along the anterior–posterior axis to accommodate the increase in oocyte volume during nurse cell dumping (Spradling, 1993; Dobens and Raftery, 2000) (see **Chapter 1.2**).

The patterning and movements of the follicular epithelium are controlled by several autocrine and paracrine signaling pathways. Thus, the "Janus Kinase/Signal Transducer and Activator of Transcription" (JAK/STAT) pathway is responsible for border cell specification and migration between the cells of the nurse cell complex (Castelli-Gair Hombría and Brown, 2002). Furthermore, migration toward the oocyte is guided by spatial cues that are detected by the *Drosophila* homologs of the mammalian platelet-derived growth factor receptor/vascular endothelial growth factor receptor (PDGFR/VEGFR) and the epidermal growth factor receptor (EGFR) pathways (Rørth, 2002). The best known transcription factor necessary for border cell migration is Slow border cells (SLBO), a basic region/leucine zipper transcriptional activator related to the mammalian CCAAT/enhancer-binding protein (C/EBP) transcription factors (Montell, 2001). Interestingly, temporal cues for border cell migration seem to be initiated by components of the ecdysone receptor signaling, such as the USP nuclear receptor and the p160 class of the nuclear receptor coactivator Taiman (Tai; Montell, 2001). Nevertheless, the findings that *tai* or *usp* mutants show deficiencies in border cell migration do not necessarily prove an involvement of ecdysone, since both USP and Tai could act as components of other signaling pathways (see discussion in Section 1.3.3.1.1.1.3; also Swevers and Iatrou, 2003). From a comparative viewpoint, it should be noted that the specification of a group of apical follicular cells that migrate through the cells of the nurse cell complex to reach the oocyte surface (border cells), is specific to the order of the Diptera and does not occur in species of other insect orders (Büning, 1994).

The formation of anterior structures in the eggshell, mediated by the centripetally migrating and border cells, is controlled by the transforming growth factor β/Decapentaplegic (TGFβ/Dpp) and the epidermal growth factor (EGF) pathways (Twombly *et al*., 1996) (see **Chapter 1.2**). The cells at the leading edge of the centripetally migrating population produce Dpp during migration and micropyle formation (Twombly *et al*., 1996; Dobens *et al*., 2000). EGF signals, alternatively, emanate initially from the oocyte nucleus at the dorsal-anterior part of the oocyte, and are subsequently modulated by autocrine signaling in the dorsal-anterior follicular epithelium (Stevens, 1998; Van Buskirk and Schüpbach, 1999). Overexpression experiments have shown that correct patterning of the anterior part of the follicular epithelium/eggshell is dependent on the integration of both Dpp and EGF signaling (Dobens and Raftery, 2000).

1.3.3.7. Nurse Cell Dumping and Apoptosis

The process of rapid transport of the contents of the nurse cells to the oocyte at the end of vitellogenesis that is accompanied by programmed cell death in the nurse cells, has been described in detail and subjected to genetic analysis in *D. melanogaster* (review: **Chapter 1.2**). In other insect species, it is not known whether these processes are regulated by mechanisms analogous to those occurring in *Drosophila* or by different pathways.

In *Drosophila*, the nurse cell cytoplasm is rapidly transported to the oocyte during stages 10B and 11 of oogenesis. This results in the doubling of the oocyte volume in about 30 min. Concomitantly, circular streaming is initiated in the cytoplasm of the oocyte that effects the rapid mixing of the nurse cell contents with the cytoplasm of the oocyte (Mahajan-Niklos and Cooley, 1994).

The transport of the contents of the nurse cell cytoplasm is regulated by the actin cytoskeleton, which performs two functions. First, the cortical actin cytoskeleton together with a myosin motor generates the driving force required to expel the nurse cell cytoplasm (Wheatley *et al*., 1995; Edwards and Kiehart, 1996). Second, actin bundles anchor the nurse cell nuclei to the membrane, thus preventing them from blocking the path of cytoplasmic flow through the ring canals (Cooley *et al*., 1992; Cant *et al*., 1994; Matova *et al*., 1999).

The process of dumping of the cytoplasmic contents of the nurse cells to the oocyte is closely associated with the initiation of programmed cell death (apoptosis) in the nurse cell complex. Loss of function of the *dcp-1* gene, which encodes an effector caspase involved in apoptosis, results in defects in nurse cell dumping, suggesting that apoptosis is a necessary event for the final transport of the nurse cell contents into the oocyte (McCall and Steller, 1998). After the majority of the cytoplasm is lost from the nurse cells, DNA breakdown occurs in the nurse cell nuclei during stage 13, and the nurse cell remnants are removed via phagocytosis by the follicular cells at stage 14 (Foley and Cooley, 1998; Cavaliere *et al*., 1998; Nezis *et al*., 2000). The activities of the regulators of the death process (interplay between caspases and caspase inhibitors) are proposed to be temporally and spatially controlled, since the oocyte must be protected from the death process that occurs in the connected nurse cells (Peterson *et al*., 2003).

Nurse cell dumping and apoptosis must also be tightly coordinated with the morphogenetic movements in the follicular epithelium, to allow the appropriate formation of a continuous epithelium that

will seal the oocyte completely for deposition of the chorion or eggshell. The signaling pathways, between the germline and the cells of the follicular epithelium that coordinate these processes, include the c-Jun-NH_2-terminal kinase (JNK) pathway (Dequier *et al.*, 2001; Dobens *et al.*, 2001) and others that may involve GPCRs and cAMP signaling (Schneider and Spradling, 1997; Lannutti and Schneider, 2001; Pathirana *et al.*, 2001).

1.3.3.8. Vitelline Membrane Synthesis

1.3.3.8.1. Dipteran insects

1.3.3.8.1.1. ***Drosophila melanogaster*** To date, four *Drosophila* vitelline membrane protein (VMP) genes have been cloned, *VM26A.1, VM26A.2, VM34C*, and *VM32E* (Higgins *et al.*, 1984; Mindrinos *et al.*, 1985; Burke *et al.*, 1987; Popodi *et al.*, 1988; Gigliotti *et al.*, 1989). While *VM26A.1, VM34C*, and *VM26A.2* are expressed continuously from stages 8 to 10, *VM32E* is considered to be a “late” gene and is expressed only at stage 10. Furthermore, *VM34C* and *VM32E* are not expressed in the polar follicular cells, in contrast to *VM26A.1* and *VM26A.2*. However, upon synthesis and secretion, both proteins have been postulated to diffuse towards the poles of the follicles (Andrenacci *et al.*, 2001).

For the *VM26A.1* and *VM32E* genes, analysis of their promoter regions has been carried out in transgenic flies, and *cis*-regulatory elements for temporal and spatial regulation as well as expression levels have been delineated (Gargiulo *et al.*, 1991; Jin and Petri, 1993; Cavaliere *et al.*, 1997; Andrenacci *et al.*, 2000). However, no *trans*-acting factors that regulate the expression of the *VMP* genes have been identified thus far.

Immuno-electron microscopy and confocal immunofluorescence studies have shown that yolk proteins (Yps) and VMPs are co-secreted by the cells of the follicular epithelium (stages 9 and 10 of oogenesis). While the VMPs are incorporated in the incomplete vitelline membrane (VM) matrix, the YPs diffuse through gaps in the vitelline layer to reach the oocyte surface. During stage 10B, the incomplete parts of the VM fuse to form a continuous layer that covers completely the oocyte surface (Margaritis, 1985; Trougakos *et al.*, 2001).

All VMPs become localized in the VM during choriogenesis. However, during the later stages, VM32E (but not the other VMPs) is capable of moving from the VM layer to the endochorion (which is secreted during stages 11–14), indicating its participation in the formation of endochorion structures (Andrenacci *et al.*, 2001). The VMPs also undergo proteolytic processing during choriogenesis (Pascucci *et al.*, 1996), but the functional relevance of this finding remains obscure.

The VMPs are characterized by a conserved hydrophobic domain of 38 aa, the VM domain (Scherer *et al.*, 1988) which is necessary for their assembly in the VM. Alternatively, the domain responsible for the localization of the VM32E protein to the endochorion during choriogenesis resides at the C-terminus of the protein (Andrenacci *et al.*, 2001).

In the female sterile mutation *fs(2)QJ42*, the follicles fail to accumulate VM26A.2, and this results in the formation of an altered VM, onto which the endochorion layer collapses during stage 14 (Savant and Waring, 1989). Thus, the preformation of a properly assembled VM is a prerequisite to the formation of a stable chorion structure (Pascucci *et al.*, 1996).

Another genetic locus implicated in vitelline membrane and chorion formation in *Drosophila* is the *defective chorion-1* (*dec-1*) locus (Waring *et al.*, 1990). The *dec-1* gene encodes multiple protein products that are generated by alternative splicing and protein processing. Three proproteins, fc177, fc125, and fc106, are produced that share a common N-terminus but are distinguished by differential C-termini. Following their secretion, the proproteins undergo distinct extracellular maturation pathways: fc106 is processed during stage 10B into s80, which undergoes an additional cleavage that generates s60 during stage 14; fc125 is initially cleaved to a 125 kDa protein at stage 10A and subsequently to 110 and 95 kDa proteins during stage 10B; and fc177 undergoes a cleavage to a 125 kDa and a second one that yields an 85 kDa protein during stages 12 and 13, respectively (Noguerón and Waring, 1995; Noguerón *et al.*, 2000). The DEC-1 proteins are synthesized concomitantly with the VMPs and accumulate extracellularly between the follicular epithelium and the oocyte. The VM functions both as the site where the proteolytic cleavage products are generated and as a reservoir for the release of the different cleavage products to the oocyte and distinct regions of the chorion, where they presumably exert unique functions (Noguerón *et al.*, 2000). Mutants of *dec-1* fail to organize the endochorion, which, as is the case of the *fs(2)QJ42* mutation, collapses into the VM during late choriogenesis (Waring *et al.*, 1990).

Recently, the distinct functions of the three DEC-1 proproteins were also dissected genetically. Using specific *dec-1* mutations, in conjunction with introduced *dec-1* transgenes, it was shown that gross morphological abnormalities occur only in the absence of fc177, although all three proproteins are essential for female fertility. It was proposed that fc177 acts as a scaffolding protein necessary for the

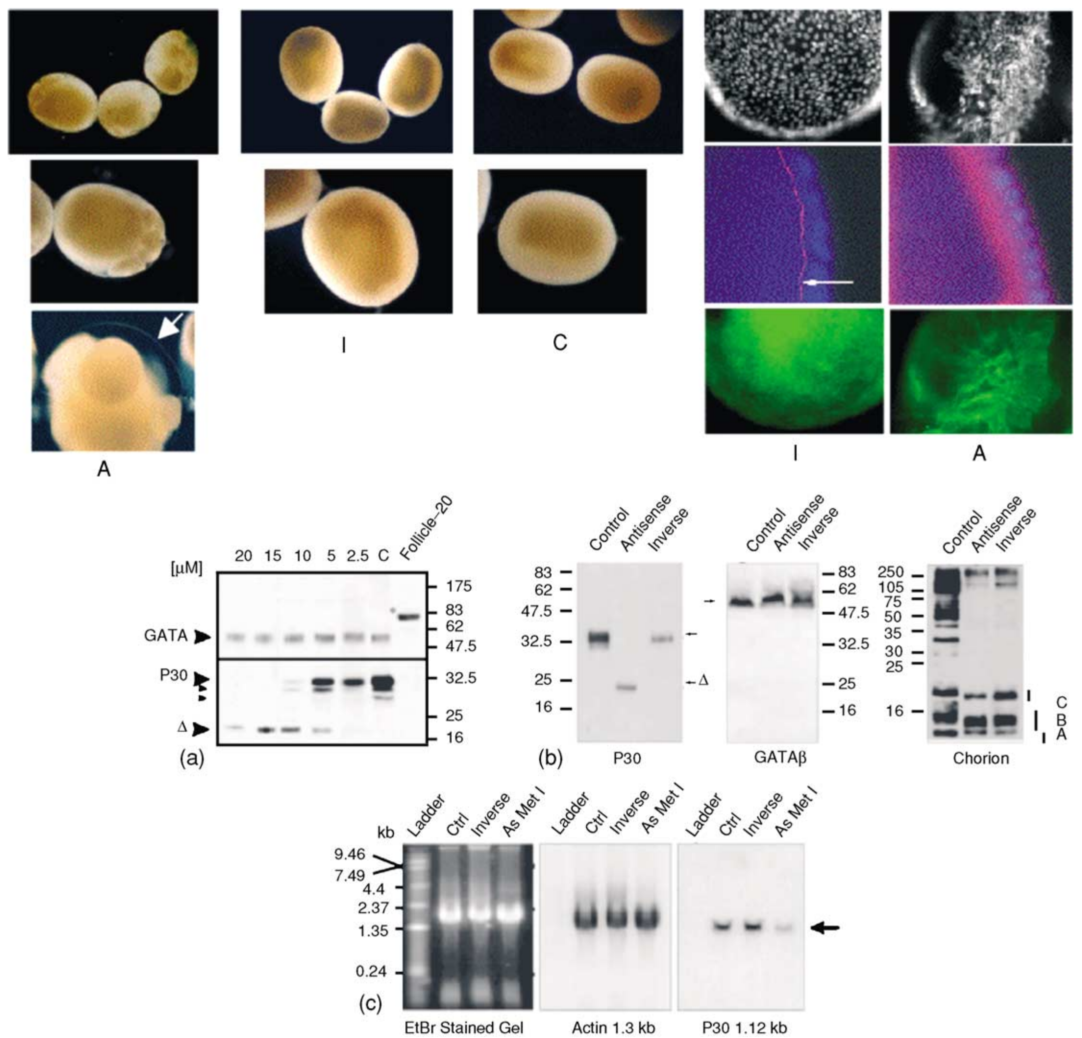

Figure 16 Functional analysis of the *BmVMP30* gene of *Bombyx mori* that encodes a putative member of the insect vitelline membrane protein family. Follicles were treated with antisense or control (inverse) oligonucleotides and the effects of the treatments on the morphology of the follicles and the expression of *BmVMP30* and other genes were assessed. Upper left panel: Light microscopy observations of the integrity of the follicular epithelium and the oocyte of developing follicles following treatment with 15 μM of antisense oligonucleotide (panel A) or control (inverse) oligonucleotide (panel I) or without treatment (panel C) for 48 h *in vitro*. Note the abnormal distribution of the yolk within the antisense oligonucleotide-treated follicles (white arrow in bottom panel of panel A). Upper right panel: Fluorescence microscopy observations of the integrity of the follicular epithelium and the oocyte of developing follicles following treatment with 15 μM of antisense oligonucleotide (panel A) or inverse oligonucleotide (panel I) for 48 h *in vitro*. Follicles were stained with DAPI (top) or stained with fluorescent anti-BmVMP30 (middle) or anti-tubulin (bottom) antibody complexes. While follicles treated with inverse oligonucleotide retain their wild-type appearance, disruptions of the follicular epithelium occur after treatment with antisense oligonucleotide. In panel A, note the disruption of the follicular epithelium characterized by gaps in the nuclear staining (top right), diffuse localization of BmVMP30 epitopes within the follicular cells (middle right), and a nonhomogeneous tubulin staining (bottom right). The normal location of BmVMP30 and the vitelline membrane (wild-type appearance) is marked by a white arrow in the left middle panel (bar = 50 μm). Bottom panel: Western and Northern blot analysis of the expression of *BmVMP30* and other genes after treatment of follicles with BmVMP30 antisense and control oligonucleotides. (a) Western blot demonstrating the effects of different concentrations (2.5 to 20 μM) of BmVMP30 antisense oligonucleotide on BmVMP30 (P30) protein expression after *in vitro* culture of middle/late (stage ''−20'') vitellogenic follicles for 48 h. No BmVMP30 was initially detected in mid-vitellogenic follicle ''−20'' prior to culture (right-most lane). Arrows point to truncated BmVMP30 proteins presumed to originate from the use of alternative translation start sites; ''Δ'' indicates the presence of the putative truncated ΔBmVMP30 protein. While the antisense oligonucleotides had profound effects on BmVMP30 protein expression (lower), no changes were observed in the expression of the 55 kDa BmGATAβ protein (upper). Note that the BmGATAβ antiserum recognizes an additional unknown ∼70 kDa protein in ''−20'' follicles (star). C, control ''−20'' follicles cultured *in vitro* for 48 h in the absence of antisense oligonucleotide. Molecular weight markers are indicated at right. (b) Western blot demonstrating the effects of 15 μM of antisense or inverse oligonucleotide on BmVMP30 (P30) (left), BmGATAβ (middle), or chorion protein (right) expression after *in vitro* culture of middle/late vitellogenic follicles (stage ''−20'') for 48 h. The presence of BmVMP30, ΔBmVMP30 (Δ), and BmGATAβ proteins are indicated by arrowheads while the different chorion protein families (A, B, C) are indicated by bars. Numbers refer to molecular weights (kDa) of protein markers. (c) Northern blot analysis demonstrating the effects of 15 μM of

erection of the chorion structure (Mauzy-Melitz and Waring, 2003).

The VM represents also a storing site for secreted follicular epithelium cell products involved in embryonic pattern formation (see **Chapter 1.2**). Extracellular proteins that signal the patterning of the embryo are anchored in the VM and participate actively in the VM assembly. The Nudel protease, for example, a large modular protein with a trypsin-like serine protease domain, functions both in the generation of the extracellular signal that determines the dorsoventral axis of the embryo, and the cross-linking of the vitelline membrane (LeMosy *et al*., 1999; LeMosy and Hashimoto, 2000). Similarly, the *fs(1)Nasrat* and *fs(1)polehole* genes are not only required for the generation of the ligand for the local activation of the Torso (TOR) receptor at the termini of embryos, but also have structural roles in the biogenesis of the VM (Cernilogar *et al*., 2001).

1.3.3.8.1.2. **Aedes aegypti** Three genes encoding VMPs have been cloned in *A. aegypti*, *15a-1*, *15a-2*, and *15a-3* (Lin *et al*., 1993; Edwards *et al*., 1998). All are characterized by a short 46 aa sequence that bears similarities with the VM domain of the *Drosophila* VMPs. The expression patterns of the vitelline membrane proteins during oogenesis overlap those of the YPs. *In situ* hybridization has also shown that the different *VMP* genes are expressed in spatially distinct domains of the follicular epithelium: *15a-1* and *15a-3* are expressed in the middle and the posterior regions of the follicle, while *15a-2* is expressed over the entire surface (Edwards *et al*., 1998). Finally, a moderate stimulation of expression levels of the VMPs could be achieved by addition of high concentrations 20E (Lin *et al*., 1993; Edwards *et al*., 1998).

1.3.3.8.2. Lepidopteran insects In general, and in contrast to chorion formation (Section 1.3.4), very little is known about vitelline membrane formation in lepidopteran insects at the molecular level. In the best studied lepidopteran model, the domesticated silkmoth *B. mori*, for example, only one vitelline membrane protein gene has been isolated and characterized in detail (see below).

1.3.3.8.2.1. **Bombyx mori** A cDNA clone, *BmVMP30*, encoding a putative VMP has been isolated from a screen for genes that are differentially expressed with respect to stages −35/−1 (Kendirgi *et al*., 2002). BmVMP30 is a 30 kDa protein that is synthesized and secreted by the cells of the follicular epithelium during late vitellogenesis (stages −18 to −1). The protein accumulates between the oocyte surface and the follicular epithelium, where the VM is located (**Figure 16**), and remains associated with the egg envelope during choriogenesis and after egg-laying. However, after fertilization no BmVMP30 protein could be detected by Western blot analysis in the eggshell fraction of the developing embryos. Thus, the temporal and spatial expression pattern of BmVMP30 during and after oogenesis is consistent with the behavior expected for a VMP (Kendirgi *et al*., 2002). Although BmVMP30 does not have significant sequence identity with any *Drosophila* or mosquito VMPs, including the VM domain, it does share with them a distinct overall proline distribution, a similar general hydropathy profile and the lack of introns in the gene structure (Kendirgi *et al*., 2002).

Strong knockdowns of *BmVMP30* gene expression, achieved by antisense oligonucleotide technology, resulted in the appearance of a severe phenotype suggesting disruption of the integrity of the follicular epithelium, while no interference was observed with the initial steps of the program that controls the activation of chorion protein genes (**Figure 16**; Kendirgi *et al*., 2002). Because the knockdown experiments were carried out in *in vitro* culture, the long-term effects on follicle development and eggs (e.g., completion of choriogenesis) could not be assessed.

The expression of *BmVMP30* requires downregulation of the 20E signaling, as its mRNA is not observed in ovaries that are treated with the 20E agonist tebufenozide (Swevers and Iatrou, 1999; see also Section 1.3.4.1.1.2). Interestingly, *BmVMP30* gene expression becomes upregulated during follicular development concomitantly with that of the orphan nuclear receptor BmFTZ-F1, suggesting a possible regulation of the expression of *BmVMP30* by BmFTZ-F1 (Swevers and Iatrou, 1999, 2003).

1.3.4. Choriogenesis

The deposition of the eggshell or chorion occurs when the cells of the follicular epithelium undergo their terminal differentiation and become devoted to the

antisense (AsMet1) or inverse oligonucleotide on BmVMP30 (P30) and actin mRNA expression after *in vitro* culture of middle/late vitellogenic follicles (stage "−20") for 48 h. The specific reduction of BmVMP30 mRNA by antisense oligonucleotide treatment is indicated by an arrow. RNA molecular weight markers are indicated on the left. EtBr, ethidium bromide; Ctrl, control. (Reprinted by permission of Federation of the European Biochemical Societies from An ovarian follicular epithelium protein of the silkworm (*Bombyx mori*) that associates with the vitellise membrane and contributes to the structural integrity of the follicle, by Kendirgi, F., Swevers, L., Iatrou, K., *FEBS Letters* 524, 59–68, © 2002.)

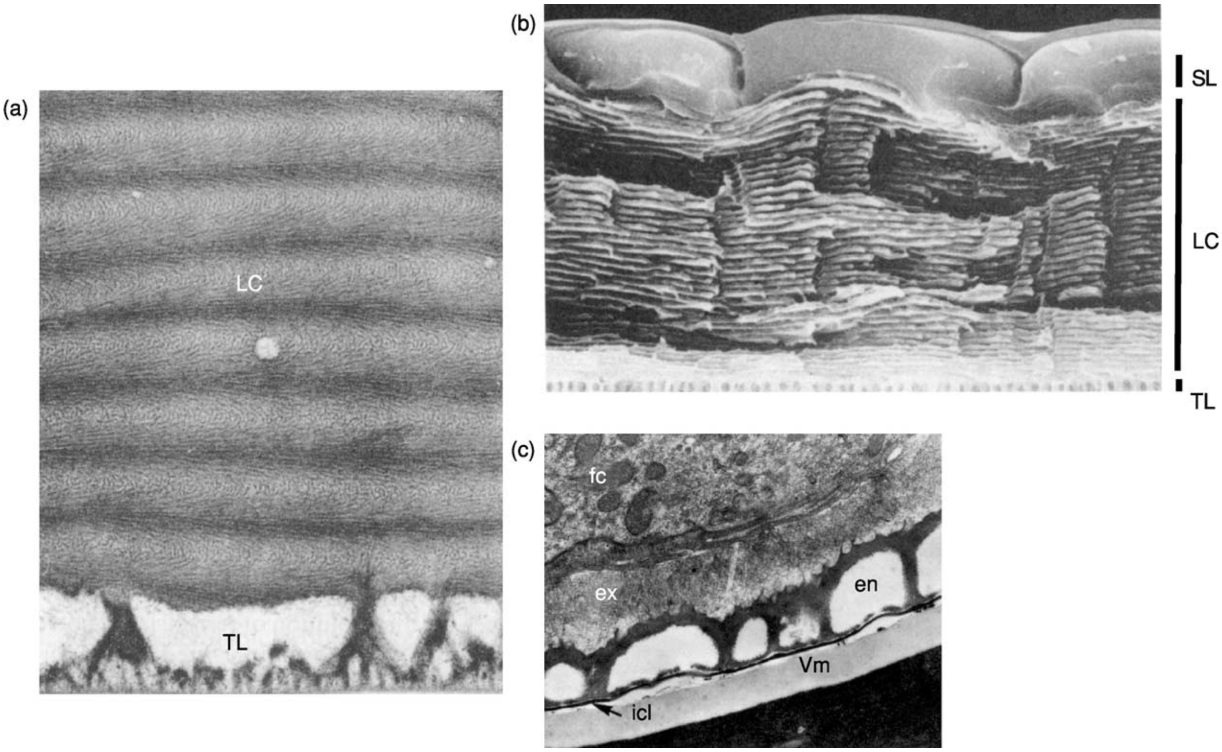

Figure 17 Chorion structure of eggs from *Hyalophora cecropia* (a), *Bombyx mori* (b), and *Drosophila melanogaster* (c). (a) Transmission electron micrograph of an immature chorion from the silkmoth *H. cecropia*. The trabecular layer (TL) is at the bottom with a portion (approximately 6% of total) of the helicoidal lamellae (lamellar chorion, LC) above. Magnification = 30 000×. (Reprinted from Regier, J.C., Friedlander, T., Leclerc, R.F., Mitter, C., Wiegmann, B.M., **1995**. Lepidopteran phylogeny and applications to comparative studies of development. In: Goldsmith, M.R., Wilkins, A.S. (Eds.), Molecular Model Systems in the Lepidoptera. Cambridge University Press, Cambridge, pp. 107–137, with permission from Cambridge University Press.) (b) Scanning electron micrograph of a transverse rip through the mature eggshell of *B. mori*. Indicated are the different chorion layers: the small trabecular layer (TL) is located at the side of the vitellin membrane and the oocyte, while the bulk of the chorion consists of multiple horizontal lamellae (LC). At the top (external surface), a few specialized surface lamellae (SL) are deposited. Magnification = 2000×. (Reprinted from Kafatos *et al*., 1985, with permission from Cold Spring Harbor Laboratory Press.) (c) Transmission electron micrograph of a section of a stage 14 follicle of *D. melanogaster* showing the structure of the eggshell. The oocyte (o), vitellin membrane (Vm), inner chorionic layer (icl), endochorion (en), exochorion (ex), and overlying follicle cell (fc) are indicated. Magnification = 150 000×. (Reprinted from Spradling, A.C., **1993**. Developmental genetics of oogenesis. In: Bate, M., Martinez Arias, A. (Eds.), The Development of *Drosophila melanogaster* vol. 1. Cold Spring Harbor Laboratory Press, Cold Spring Harbor, NY, pp. 1–70, with permission from Cold Spring Harbor Laboratory Press. Photo courtesy of Drs. G. Waring and A. Mahowald.)

synthesis and secretion of the chorion proteins, which subsequently become assembled extracellularly into a large macroscopic structure (Orr-Weaver, 1991; Kafatos *et al*., 1995). The insect eggshell is a complex structure that protects the developing embryo in a hostile environment (**Figure 17**). Although water loss should be minimized to prevent desiccation, the eggshell should provide sufficient gas exchanges to allow embryo respiration. Eggshells therefore contain specialized regions that facilitate gas exchange between the embryo and the environment. Examples of such specialized structures for air transport include the dorsal appendages at the dorsal-anterior part of the egg surface, and the aeropyles at the posterior pole of the *Drosophila* egg. The eggshell also contains other specialized structures: at the anterior end are located both the micropyle, that forms a channel through the eggshell that allows the sperm to enter the oocyte surface for fertilization, and the operculum, which functions as the door through which the larva will exit the eggshell (Spradling, 1993).

Choriogenesis has been studied mostly in dipteran and lepidopteran insects, most notably in *D. melanogaster* and *B. mori* (Kafatos *et al*., 1995). The process of choriogenesis differs substantially between flies and moths: the structure of the *Drosophila* chorion is relatively simple and is composed of six major and 14 minor proteins (Kafatos *et al*., 1985, 1995); the silkmoth chorion, alternatively, is a more complex structure, consisting of more than 100 different polypeptides and becoming assembled in a stepwise fashion over a period of approximately 2 days (Kafatos *et al*., 1977, 1985, 1995). Similar complex chorion structures are

observed in other lepidopteran insects of the Bombycoidea superfamily (Regier *et al.*, 1995). Recently, the structure of the chorion of a coleopteran insect, the Colorado potato beetle *Leptinotarsa decemlineata*, has been also presented (Papassideri *et al.*, 2003).

The evolution of the structure of the chorion in lepidopteran insects has also been reviewed (Regier *et al.*, 1995), and the principles that govern the molecular architecture of helicoidal proteinaceous eggshells of the Lepidoptera have described in detail by Hamodrakas (1992). Interestingly, Hamodrakas and his collaborators have provided evidence that the silkmoth eggshell may be a natural protective amyloid (Iconomidou *et al.*, 2000), and described how these amyloids are formed *in vitro* via a liquid crystalline mesophase (Hamodrakas *et al.*, 2004; see also **Chapter 4.2**).

After secretion of the chorion proteins and assembly of the eggshell, the latter becomes stabilized through an extensive crosslinking process that involves peroxidase activity. Peroxidase catalyzes the formation of di- and tri-tyrosyl crosslinks among chorion proteins, a process that strengthens the eggshell. The peroxidase activity is initiated through the production of hydrogen peroxide by the cells of the follicular epithelium (Margaritis, 1985; Han *et al.*, 2000). In mosquitos, the process of chorion tanning (melanin formation) requires tyrosine as well as the action of the enzymes phenol oxidase and dopa decarboxylase (Li, 1994; Ferdig *et al.*, 1996).

1.3.4.1. Chorion Genes and Regulation of Chorion Gene Expression

The early studies on the topic have been reviewed extensively in the past (Regier *et al.*, 1995; Eickbush and Izzo, 1995; Goldsmith and Kafatos, 1984; Kafatos *et al.*, 1987, 1995). In this section, most recent information related to the structure of chorion genes and the regulation of their expression is reviewed, which has been obtained through the study of the two major insect models, the fruit fly *D. melanogaster*, and the silkmoth, *B. mori*.

1.3.4.1.1. *Drosophila melanogaster* Starting from the VM and moving in an outward fashion, the *Drosophila* chorion consists of four layers, the wax layer, the innermost chorionic layer (ICL), the endochorion, and the exochorion (**Figure 17**; Spradling, 1993; Trougakos and Margaritis, 1998). The chorion consists mainly of six major and 14 minor proteins. The genes that encode two major and four minor proteins (s36, s37, s38, A, B, C) are clustered on the X chromosome (region 7F1; Parks *et al.*, 1986; Orr-Weaver, 1991), while those for the four other major proteins (s15, s16, s18, s19) are encoded in a cluster on chromosome 3 (region 66D11-15; Kafatos *et al.*, 1985, 1995). The general features of the chorion genes are their organization in tandem arrangement in both clusters (**Figure 18**), the presence of a small intron near the 5′-end of each gene, and the presence of repeated sequences in the protein coding regions.

The genes on the X cluster are considered "early" genes, since they are expressed during stages 11–13 of oogenesis, when the ICL and endochorion components are produced. The genes on the third chromosome cluster, however, are expressed during stages 13 and 14, when the exochorion is deposited and, thus, represent "late" genes (Mariani *et al.*, 1988; Tolias and Kafatos, 1990). While the chorion proteins play a structural role in chorion assembly, it has also been proposed that s38 corresponds to the eggshell peroxidase enzyme (Keramiris *et al.*, 1991). The organization of the chorion gene clusters is conserved in the Drosophilidae family and in the more distantly related medfly *Ceratitis capitata* (Vlachou and Komitopoulou, 2001).

Recently, a novel chorion protein of *Drosophila*, Femcoat, was isolated. The *femcoat* gene is expressed in the follicular cells during stages 12B to 14A of oogenesis. Double-stranded RNA-mediated RNA interference has shown that Femcoat is essential for the formation of the endochorion (Kim *et al.*, 2002).

1.3.4.1.1.1. Chorion gene amplification To accommodate the high levels of gene expression that are required for the production of the chorion during a period of only 1–2 h (stages 11–14 of oogenesis), gene amplification occurs in both chorion gene clusters of *Drosophila* (Kafatos *et al.*, 1985; Kalfayan *et al.*, 1985). The X-chromosome and third chromosome clusters are amplified 15- to 20-fold and 60- to 100-fold, respectively, above the remainder of the genome of the already polyploid (see below) cells of the follicular epithelium (Calvi and Spradling, 1999).

The selective increase in gene copy number occurs through repeated initiation of replication forks at selected sites in these loci (**Figure 18**). Because replication forks continue to move outwards as choriogenesis progresses, a gradient of amplified DNA extending 40–50 kb to either side of the chorion gene cluster is generated that can be observed as "onion-like" structures in the electron microscope (**Figure 18**) (Orr-Weaver, 1991; Royzman and Orr-Weaver, 1998).

Genetic analysis in transgenic flies identified the *cis*-regulatory elements that are required for chorion gene amplification, termed amplification controlling

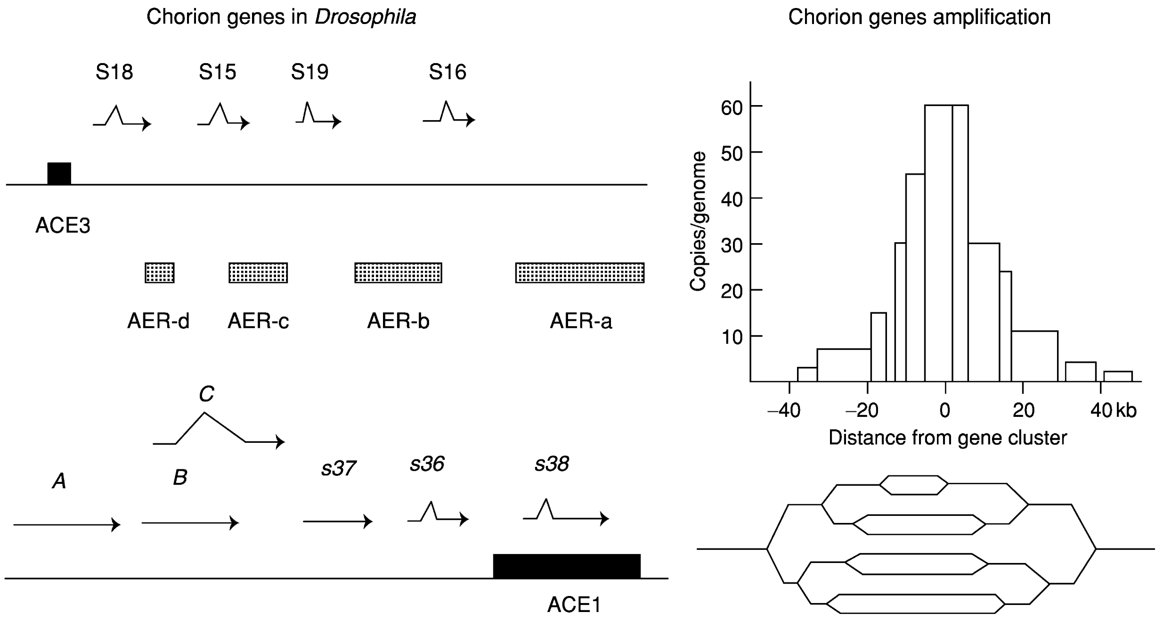

Figure 18 Chorion gene organization and mechanism of chorion gene amplification in *Drosophila*. Left panel: Structure of the chorion gene clusters. The third chromosome cluster above contains the genes for four major chorion proteins, s18, s15, s19, and s16. The X chromosome cluster below contains two major chorion genes, *s36* and *s38*, as well as several genes that encode minor chorion proteins (*A*, *B*, *C*, and *s37*). The positions of the transcripts are shown by the lines with arrows. Introns are indicated except for *A*, *B*, and *s37*, for which introns have not been mapped. The position of the amplification regulatory regions, AERs a–d (amplification enhancing regions a–d), and ACE1 (amplification control element 1), are also indicated. Right panel: Chorion gene amplification results from multiple rounds of reinitiation of DNA replication within the chorion gene cluster and progressive movement of replication forks to either side. Above is shown the level of amplification of DNA fragments at various distances from the origin of replication. Below is illustrated the ''onion-like'' structure of the nested bi-directional replication forks that are observed during chorion gene amplification. (Reprinted from Orr-Weaver, T.L., **1991**. *Drosophila* chorion genes: cracking the eggshell's secrets. *BioEssays 13*, 97–105.)

elements and amplification-enhancing regions (ACEs and AERs, respectively; **Figure 18**) (Kalfayan *et al*., 1985; Spradling *et al*., 1987; Delidakis and Kafatos, 1987; Swimmer *et al*., 1989; Lu *et al*., 2001). The origin of replication (Ori-β) within the third chromosomal cluster was also identified by two-dimensional gel electrophoresis (Delidakis and Kafatos, 1989; Heck and Spradling, 1990). Analysis of thin chorion mutants has revealed the involvement of components of the DNA replication complex, such as members of the origin recognition complex (ORC), Cdc7-Dbf4 kinase, double-parked protein (Dup)/Cdt1, and the minichromosome maintenance (MCM) protein complex (Landis *et al*., 1997; Landis and Tower, 1999; Claycomb *et al*., 2002; Schwed *et al*., 2002).

The initiation of chorion gene amplification is under cell cycle control. During their developmental career, two major switches in cell cycle control occur in the cells of the follicular epithelium. The follicular cells undergo mitotis until stage 6 of oogenesis, after which they undergo three endocycles (cycles consisting only of an S phase and a gap phase) and become polyploid (16N; Calvi *et al*., 1998; see **Chapter 1.2**). At the beginning of choriogenesis, the endocycles cease and DNA amplification is initiated at specific sites in the genome where the chorion gene clusters are located. The cyclin E cell cycle regulator plays a major role in orchestrating this transition: at the transition to choriogenesis, cyclin E switches from a cycling pattern of expression to continuous high expression in all follicle cell nuclei. It has been proposed that continuous high levels of cyclin E prevent general DNA replication in the follicular cell genome, while specific factors recruited at the chorion gene origins allow the latter to escape this negative replication control (Calvi *et al*., 1998). Factors that are involved in restricting or recruiting the replication machinery, specifically to the chorion origins of replication, are proposed to include the S-phase regulator E2F/DP/Rbf (Royzman *et al*., 1999; Cayirlioglu *et al*., 2001; Bosco *et al*., 2001) and a Myb (Myeloblastosis)-containing protein complex (Beall *et al*., 2002).

1.3.4.1.1.2. cis-Regulatory elements and factors that bind chorion gene promoter elements Promoter analysis in transgenic flies has been carried

out mainly for the *s15* and *s36* chorion genes, and *cis*-regulatory elements for temporal, spatial, and quantitative control have been delineated (Spradling, 1993; Kafatos *et al*., 1995). Short (less than 100–400 bp) segments of 5′-flanking DNA are sufficient to confer correct tissue-specific expression and precise temporal regulation of the transgenes (Mariani *et al*., 1988; Romano *et al*., 1988). *Cis*-acting regulatory elements, identified by mutational analysis, include an essential positive element, characterized by the sequence TCACGT that is conserved in all the chorion gene promoters, negative and positive elements that confer temporal (early or late) specificity, and elements defining spatially restricted expression (review: Orr-Weaver, 1991; Tolias *et al*., 1993; Mariani *et al*., 1996). In the latter case, the elements delineate expression in specific subregions of the epithelial surface, notably at the anterior and posterior poles and at the dorsal-anterior surface, where the dorsal appendages are formed (Parks and Spradling, 1987; Tolias and Kafatos, 1990).

Gel mobility shift assays were used to isolate putative *trans*-acting factors that bind and activate chorion gene regulatory regions (Kafatos *et al*., 1995). After a binding site was defined using nuclear extracts of choriogenic follicles, oligonucleotides encompassing the binding site were subsequently used to screen expression libraries and isolate binding proteins. This strategy resulted in the isolation of seven cDNAs that encode putative chorion gene transcription factors (chorion factors (CF) 1–7; Kafatos *et al*., 1995). Of these factors, CF1 and CF2 have been analyzed in more detail (Shea *et al*., 1990).

CF1 binds to the essential hexamer-element TCACGT. This factor was shown to correspond to the nuclear receptor USP (Henrich *et al*., 1990; Oro *et al*., 1990; Khoury-Christianson *et al*., 1992), the homolog of the vertebrate RXR receptor that functions as the heterodimer partner of the ecdysone receptor, EcR (Thomas *et al*., 1993; Yao *et al*., 1993). However, genetic analysis has shown that the involvement of CF1/USP in chorion gene expression may be more complicated than initially suggested by the DNA binding studies. Eggs laid by mutant flies that were usp^- in the germline cells (nurse cell oocyte complex) but wild-type (usp^+) in the somatic tissues (including follicular cells), showed a chorion defect, indicating that CF1/USP is required in the germline (but not in the follicular epithelium), in order to trigger the release of a signal that acts on the follicular cells and promotes chorion gene expression. *In situ* hybridization also showed that CF1/USP mRNA is abundant in the oocyte/nurse cell complexes and only barely detectable in follicular cells (Oro *et al*., 1992). The other possible roles of the EcR/USP complex during *Drosophila* oogenesis have already been discussed (Section 1.3.3.1.1.1.3).

CF2 was isolated by its property to bind the positive regulatory region that confers late temporal specificity to the *s15* promoter. It is a C_2H_2 zinc finger protein belonging to the class defined by the *Drosophila* regulatory gene *Krüppel* (*Kr*) and the mouse genes that encode the transcription factors MKR1 and MKR2 (Hsu *et al*., 1992). Genetic analysis, however, has shown that CF2 is involved in the dorsoventral patterning of the follicular epithelium (Hsu *et al*., 1996, Mantrova and Hsu, 1998). Upon activation of the epidermal growth factor receptor (EGFR) by the oocyte-derived Gurken (GRK) signal at the dorsal-anterior region of the follicular epithelium, CF2 is down-regulated by a posttranslational mechanism that involves phosphorylation by mitogen-activated protein kinase (MAPK) and subsequent cytoplasmic retention and degradation (Hsu *et al*., 1996, 2001; Mantrova and Hsu, 1998). Thus, CF2 **protein expression becomes restricted to the ventral** region of the follicular epithelium. One target gene of CF2 is *rhomboid* (*rho*), which encodes a transmembrane protein acting as a positive cofactor in EGFR signaling (Mantrova and Hsu, 1998). Because CF2 acts as a transcriptional repressor, degradation of CF2 in the dorsal cells of the follicular epithelium results in enhanced expression of RHO, which, in turn, results in the amplification of EGFR signaling levels in the dorsal-anterior follicular cells (Hsu *et al*., 1996; Mantrova and Hsu, 1998). The high levels of EGFR signaling are necessary for the formation of the dorsal appendages, the specialized chorion structures that mediate gas exchange between the environment and the embryo. In conclusion, however, as was the case with CF1, genetic analysis did not confirm a role for CF2 as a direct transcriptional regulator of the chorion genes.

Other chorion gene promoter binding factors that have been isolated and characterized include CF3, a zinc finger protein that interacts with the negative regulatory region in the *s15* promoter that is required for repression of its expression during early choriogenesis; three more factors (CF5–7) that bind the late activating region of the *s15* promoter; and CF4, which binds the early temporal element in the *s36* promoter (Orr-Weaver, 1991; Kafatos *et al*., 1995). CF5 has been shown to represent the *Drosophila* homolog of the human structure-specific recognition protein (SSRP), which belongs to the class of high-mobility-group (HMG) proteins (Hsu *et al*., 1993). HMG box-containing proteins are thought to function in processes such as DNA replication, DNA repair, and chromatin modeling, which may be involved in the regulation of transcription. The

localization of CF5 in the nucleolus and the observation that it binds single-stranded nucleic acid suggests that it may be involved in rRNA transcription through an RNA or single-stranded DNA binding mechanism (Hsu *et al.*, 1993). Therefore, the role of factor CF5 in the regulation of chorion genes, as well as that of the other factors, CF3–4 and CF6–7, is not clear at present (Kafatos *et al.*, 1995).

Recently, genetic analysis has indicated a role for the transcriptional regulator Tramtrack 69 (TTK69) in the regulation of chorion gene expression (French *et al.*, 2003). Carriers of the female sterile allele of *tramtrack* (*ttk*) called *twin peaks* (ttk^{twk}), which affects the TTK69 transcription factor, are characterized by thin eggshells, presumably due to low levels of accumulation of mRNAs of the major chorion genes. However, the defects due to loss of TTK69 are considered to be indirect, because TTK proteins are known to function as transcriptional repressors, and no binding sites could be identified within 1 kb of any of the major chorion genes (French *et al.*, 2003). It is, therefore, likely that TTK69 regulates the expression of factors upstream of the chorion genes rather than the chorion genes themselves. Besides influencing general chorion gene expression, TTK69 also has an independent genetic function in the formation of the dorsal appendages of the eggshell (French *et al.*, 2003; see also below).

1.3.4.1.1.3. Signaling pathways Formation of the anterior and dorsal structures in the eggshell, such as the operculum, the micropyle, and the dorsal appendages, are subject to multiple signaling pathways (see Section 1.3.3.6). What will be discussed briefly here are transcription factors involved in the execution of the program of the formation of the dorsal appendages, two structures at the dorsal-anterior end of the eggshell that are responsible for gas exchange.

Signals that stimulate the EGFR in the follicular cells originally emanate from the Gurken (GRK, a TGFβ homolog) signal produced by the oocyte nucleus that is located at the dorsal-anterior end of the oocyte. Positive and negative feedback loops of signaling at the dorsal-anterior surface ultimately result in two patches of follicular cells, where high levels of EGFR signaling (Ras and MAPK activity) occur. These two patches of follicular cells are destined to form the dorsal appendages of the eggshell (Wasserman and Freeman, 1998; reviews: Stevens, 1998; Van Buskirk and Schüpbach, 1999).

Dorsal appendage formation can be divided in two stages; first, an initiation phase, during which the two groups of dorsal-anterior follicular cells move outward from the rest of the follicular epithelium and form a short tube overlying the junction between oocyte and nurse cells (stages 10B to 12 of oogenesis); and second, an elongation phase, during which the two tubes extend to their full lengths (French *et al.*, 2003). The transcription factors Broad-Complex (BR-C), Pointed (PNT), and CF2 seem to have a role during the initiation phase of dorsal appendage formation.

Broad-Complex is a transcription factor characterized by C-terminally located C_2H_2 zinc fingers and an N-terminal Broad-Complex/Tramtrack/Bric-à-Brac (BTB) or poxvirus and zinc finger (POZ) domain, which appears to be involved in protein–protein interactions (DiBello *et al.*, 1991; Collins *et al.*, 2001; see also **Chapter 1.8**). The Z1 isoform of BR-C becomes expressed in the patches of follicular cells destined to form the dorsal appendages, and may be an upstream regulator of this process (Huang and Orr, 1992; Deng and Bownes, 1997).

Pointed is an ETS domain-containing transcription factor that is induced at the stage, when the highest levels of EGFR signaling occur. The expression of PNT results in a downregulation of the EGFR pathway, possibly through the induction of the expression of Argos (AOS), a putative extracellular inhibitor of EGFR (Schweitzer *et al.*, 1995; Morimoto *et al.*, 1996). The result of the action of PNT is the splitting of the original EGFR signaling area into two symmetrical patches across the dorsal midline of the egg, which will generate the two dorsal appendages.

As already mentioned earlier, CF2 is a transcriptional repressor whose expression is downregulated by EGFR signaling. Downregulation of CF2 results in the induction of RHO expression, which is involved in the amplification of the EGFR signal (Hsu *et al.*, 1996; Mantrova and Hsu, 1998).

Finally, the Jun N-terminal kinase (JNK) cascade is involved in the correct execution of the extension phase of dorsal appendage formation (Dequier *et al.*, 2001; Suzanne *et al.*, 2001; French *et al.*, 2003). Members of the JNK cascade include the *Drosophila* Jun N-terminal kinase kinase (DJNKK) or Hemipterous (HEP), DJNK or Basket (BSK), the transcription factors Djun and Dfos, and the JNK phosphatase or Puckered (PUC). In addition, the TTK69 transcriptional repressor (see above) also acts at the extension phase of dorsal appendage formation. Finally, the JNK signaling cascade is also required in the process of micropyle formation (Suzanne *et al.*, 2001).

1.3.4.1.2. Lepidopteran insects The eggshell of lepidopteran insects constitutes a tripartite structure, consisting of the inner vitelline membrane, the chorion, and a very thin outer sieve layer (**Figure 17**;

Kafatos *et al*., 1977). The thickness of the vitelline membrane usually is <2 μm, while the chorion can vary, depending on the species, from <1 μm to >50 μm (Regier and Vlachos, 1988; Leclerc and Regier, 1993). Two regions of the chorion are easily discernible, an inner trabecular layer and a much thicker overlaying lamellar chorion (**Figure 17**). Because the lamellar zone consists of helicoidally arranged planes of fibers, it is referred to as a "helicoidal lamellar chorion" (Mazur *et al*., 1982; Regier *et al*., 1995).

The helicoidal lamellar chorion structure is restricted to ditrysian lepidopteran insects. It is absent from the other insect orders, including the sister order of the Lepidoptera, the Trichoptera (Regier *et al*., 1995). Helicoidal lamellar chorion structures and protein compositions have been studied in detail in the superfamilies of Bombycoidea (mainly *A. polyphemus* and *B. mori*), Sphingoidea (*M. sexta*), and Noctuidea (*Lymantria dispar*) (Regier and Vlachos, 1988; Leclerc and Regier, 1993; Regier *et al*., 1995).

In the superfamily of Bombycoidea, the lamellae in the helicoidal lamellar chorion can number more than 100, and they are assembled by chorion proteins that can be grouped into two branches, α and β, and that belong to six families (ErA and ErB, A and B, HcA and HcB) (Regier *et al*., 1980, 1982; reviews: Kafatos *et al*., 1995; Eickbush and Izzo, 1995; see also Section 1.3.4.1.3 below). Other substructures of the chorion, the trabecular layer at the inner surface and the specialized structures at the external surface, generally contribute to no more than 5% of the mass of the chorion and contain unique subsets of proteins.

The formation of the helicoidal lamellar chorion is proposed to occur in four temporally discrete steps, framework formation (small number of lamellae are deposited), expansion (thickening of existing lamellae), densification (thickening of fibers within lamellae), and surface sculpturing (deposition of additional lamellae that can be sculpted into surface structures, e.g., the aeropyle crowns of *A. polyphemus* eggs; Regier *et al*., 1982; Mazur *et al*., 1989; Leclerc and Regier, 1993).

The different steps can be correlated with the expression of different types of chorion proteins that are synthesized during different periods in choriogenesis. Thus, in *B. mori*, ErA and ErB proteins are produced during framework formation, A and B proteins are secreted during the expansion and densification processes, and the formation of specialized outer lamellae is dependent on HcA and B proteins (see Section 1.3.4.1.3 below). The evolution of the chorion structure within ditrysian lepidopteran insects is proposed to have occurred by shifts in the timing and the intensity of protein synthesis in the four steps of assembly of the helicoidal lamellar chorion (Regier *et al*., 1995).

1.3.4.1.3. *Bombyx mori* The chorion or eggshell of *B. mori* (**Figure 17**) is an elaborate structure consisting of more than 100 polypeptides that are produced and secreted by the follicular cells during their terminal differentiation (Nadel *et al*., 1980; Iatrou *et al*., 1982). The chorion polypeptides are of low molecular weight (10–25 kDa) and have a tripartite structure consisting of a highly conserved central domain that is class-specific (A or B, see below), flanked by more variable left and right arms (Tsitilou *et al*., 1983). Sequence analysis reveals that chorion genes belong to a single gene superfamily that can be divided into two branches, α and β (A-type and B-type members). Each branch can be subdivided into three families or ErA/ErB, A/B, and HcA/HcB (Lecanidou *et al*., 1986).

Choriogenesis in *Bombyx* occurs in four broad developmental periods. Thus, early choriogenesis is characterized by the production of the ErA and ErB proteins (stages +1 to +8 in an ovariole with a choriogenic segment of 40 follicles). Most A and B proteins are synthesized during the early-middle and late-middle periods of choriogenesis (stages +6 to +24 and +10 to +28, respectively). Finally, late choriogenesis (stages +26 to +35) involves the production of high-cysteine (Hc) proteins HcA and HcB (Bock *et al*., 1986; Spoerel *et al*., 1986).

The chorion proteins that are produced during different developmental periods have specialized functions. Early proteins form an initial scaffold, into which middle proteins intercalate to add mass and density, while late (high-cysteine) proteins percolate throughout the previously deposited lamellae to crosslink the whole chorion and, in addition, form the outer lamellate crust (Mazur *et al*., 1982; Regier *et al*., 1982, 1995).

Classical genetic analysis, using protein electrophoretic variants as genetic markers, revealed that chorion genes are organized in two clusters on chromosome 2, Ch1–2, and Ch3 (**Figure 19**), that are separated from each other by 3–4 map units (Goldsmith, 1989). The organization of the chorion genes in two clusters was confirmed after isolation of overlapping chromosomal DNA clones, corresponding to the chorion locus, from genomic libraries of *Bombyx* (**Figure 19**). From cluster Ch1–2, two contiguous chromosomal DNA segments with sizes of 270 kb and 50 kb were isolated. The 270 kb fragment has a threefold organization, in which a central 140 kb region that contains the late Hc chorion genes, is flanked by segments that contain chorion genes of early-middle and late-middle specificity

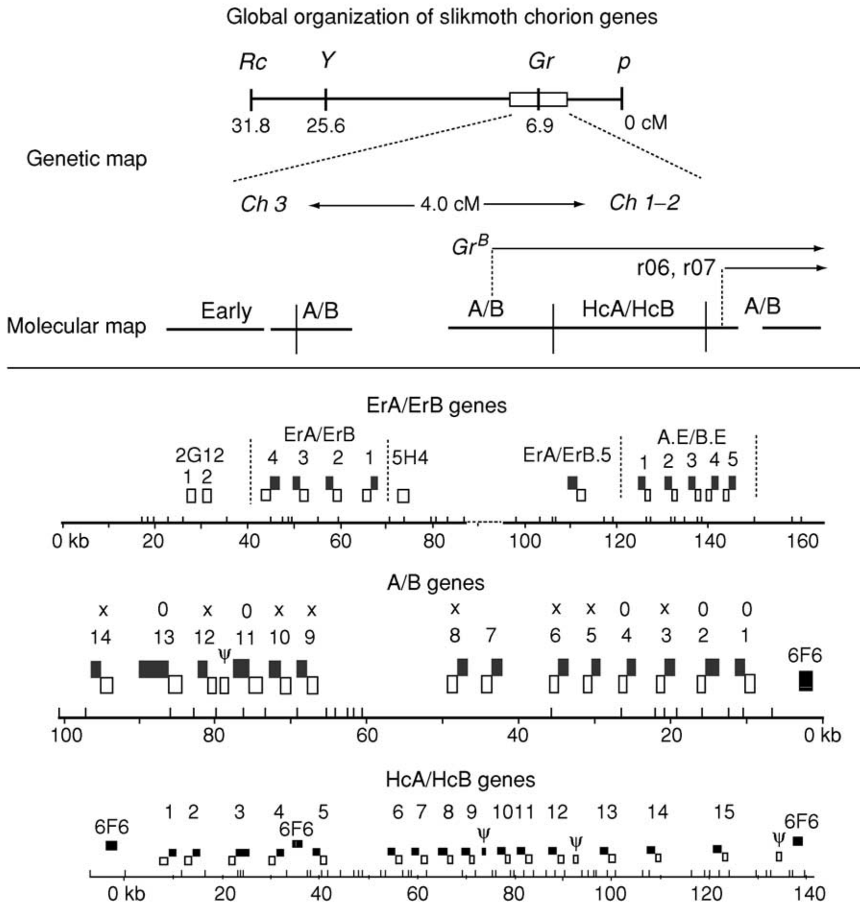

Figure 19 Chorion gene organization in *Bombyx*. Top panel: A portion of the genetic map of chromosome 2 is shown, with the genetic distances in centiMorgans (cM), for the following markers: *p*, plain larval markings; *Gr*, gray eggs; *Y*, yellow hemolymph and cocoons; and *Rc*, rusty cocoon color. The structural genes of the chorion proteins have been mapped to the gene complexes *Ch1–2* and *Ch3* (Goldsmith, 1989). Below the genetic map an overview of the molecular map is shown: the thick horizontal lines correspond to chromosomal segments from *Ch1–2* and *Ch3* that have been recovered as series of overlapping recombinant clones. The major families of chorion genes (early, A, B, HcA, and HcB) present on each cloned segment are indicated. Vertical lines on these chromosomal segments correspond to the boundaries between these gene families. An additional 80 kb of chromosomal DNA (not shown in the figure) has been recovered as a series of unlinked genomic clones containing A and B genes. The orientation and distance of the cloned segments from *Ch3* relative to that of the segments from *Ch1–2* are unknown. The segments of the *Ch1–2* complex deleted by the mutation, Gr^B, or translocated in mutants r06 and r07, are shown by the arrows above the cloned segments. Bottom panel: Organization of the early chorion gene complex (upper), the A/B gene cluster immediately to the left of the HcA/B gene cluster (middle), and the HcA/B gene cluster (lower). Filled boxes are α genes (ErA, A.E, A, and HcA) while open boxes represent β genes (ErB, B.E, B, HcB, 5H4, and 2G12). Almost all α and β genes are paired, with the exception of the 5H4 and two 2G12 genes. Pseudogenes are indicated by Ψ and the unpaired 6F6 (β branch type) genes are indicated by stippled boxes. Numbers refer to distances in kb. (Compiled from Eickbush, T.H., Izzo, J.A., **1995**. Chorion genes: molecular models of evolution. In: Goldsmith, M.R., Wilkins, S. (Eds.), Molecular Model Systems in the Lepidoptera. Cambridge University Press, Cambridge, pp. 217–247.)

(A and B genes). The 50 kb fragment also contains genes of middle developmental specificity (Eickbush and Kafatos, 1982; Spoerel *et al*., 1989). From cluster Ch3, two segments of 77 kb and 25 kb were characterized, in which early and early-middle chorion genes are present (Hibner *et al*., 1991).

The clustered organization of chorion genes on the chromosome according to their developmental specificity is intriguing, since it suggests that the different clusters may represent gene assemblies subject to common regulatory control, e.g., chromatin domains that become accessible to transcription factors at specific developmental stages (Eickbush and Kafatos, 1982; Goldsmith, 1989). Alternatively, the clustering of the chorion genes may be coincidental; it has been amply documented that diversification in the chorion locus has occurred by multiple duplication, deletion, inversion, and gene conversion events that involved relatively small patches of chromosomal DNA (Iatrou *et al*., 1984; Spoerel *et al*., 1986; Xiong *et al*., 1988;

Hibner *et al.*, 1991; review: Eickbush and Izzo, 1995). In addition, it can also be noted that three chorion genes with early developmental specificity (e.g., the 6F6 genes) are found interspersed in the Ch1–2 locus (Kravariti *et al.*, 1995), suggesting that opening of the Ch1–2 locus should occur concomitantly with the Ch3 locus and, therefore, arguing against the regulation of early versus middle and late chorion gene expression at the level of the gene cluster.

As a rule, chorion protein-encoding genes are organized in the *Bombyx* genome as gene pairs (**Figure 19**). Each gene pair consists of an A-type and B-type genes (ErA/ErB, A/B, and HcA/HcB), that undergo transcription in opposite and divergent direction from a common short (300 ± 30 bp) promoter region (Iatrou *et al.*, 1984; Spoerel *et al.*, 1986; Hibner *et al.*, 1988). Paired genes are coordinately expressed during choriogenesis (Spoerel *et al.*, 1986). Furthermore, through the use of heterologous functional assays, it has been demonstrated that the short spacer region between the two transcripts is necessary and sufficient for correct sex-, tissue-, and stage-specific expression (Mitsialis and Kafatos, 1985). A limited number of cases deviating from this rule of gene organization in pairs were also found. These involved some genes encoding early chorion genes, found in both the Ch1–2 and Ch3 clusters, which exist as single transcription units (Hibner *et al.*, 1988; Lecanidou and Rodakis, 1992; Kravariti *et al.*, 1995).

High-cysteine chorion proteins, that are synthesized during late choriogenesis, appear to be unique to *B. mori* and are not found in other silkmoths (Nadel and Kafatos, 1980). The production of high-cysteine proteins is a specialized (recently acquired during evolution) function of the *Bombyx* follicular epithelium: these proteins probably provide the eggshells with greater hardness and reduced permeability, both necessary for viability over the long periods of winter diapause (Regier *et al.*, 1995).

1.3.4.1.3.1. cis-Regulatory elements and factors that regulate chorion gene promoter elements Analysis of chorion gene expression in moths has been carried out using two different strategies. First, lepidopteran chorion promoters were cloned upstream of reporter cassettes and the activities of the chorion promoter–reporter cassettes and their mutant derivatives were assayed in transgenic *Drosophila* flies. Second, oligonucleotides encompassing chorion promoter segments were used in gel retardation assays to identify binding elements; the identification of binding sites subsequently allowed isolation of corresponding transcription factors or DNA binding proteins by homology cloning or screening of expression libraries (review: Kafatos *et al.*, 1995).

When a genomic fragment containing the early-middle gene pair *A/B.L12* was introduced into the genome of *D. melanogaster* by P-element transformation, the silkmoth genes were expressed with correct sex, tissue, and cell specificity (Mitsialis and Kafatos, 1985). Thus, *A* and *B* genes were expressed coordinately in *Drosophila*, as in *Bombyx*, and their expression patterns resembled that of the endogenous *Drosophila* late gene *s15*. Comparable results were obtained with constructs, in which the common promoter of the gene pair (300 ± 30 bp) was placed upstream of reporter genes, encoding chloramphenicol acetyl transferase (CAT) or β-galactosidase, in either orientation (Mitsialis *et al.*, 1987). It should be noted, however, that the temporal specificity was not strictly conserved between *Bombyx* and *Drosophila*, because the *A/B.L12* promoter, which is an early-middle promoter in *Bombyx*, behaved as a late promoter in *Drosophila* (Mitsialis *et al.*, 1989). Opposite shifts in temporal expression (from late to early), after introduction into the *Drosophila* genome, were also observed for chorion promoters from the moths *A. polyphemus* and *A. pernyi* (Mitsialis *et al.*, 1989).

The *cis*-regulatory elements of the bi-directional promoter of the *A/B.L12* chorion genes were defined after deletion and linker scanning mutagenesis in combination with P element-mediated genomic transformation of *Drosophila* (Mitsialis *et al.*, 1987, 1989; Spoerel *et al.*, 1993). Three important regulatory regions were detected, when mutant promoters were used in the heterologous functional assays. The regions were located asymmetrically in the promoters, and found to function in an orientation-independent manner and to have similar effects on the expression of both the A and the B genes in the pair. Thus, a TCACGT hexamer-element, located 60 bp upstream of the transcription start site of the *B* gene and found in the promoters of all silkmoth and *Drosophila* chorion genes, except the *ErA/B* genes of *Bombyx* (Hibner *et al.*, 1991; Kafatos *et al.*, 1995), was found to be absolutely necessary for expression; disruption of this element abolished expression of both the *A* and the *B* genes. Second, mutations in region A1, a 35 bp sequence located 185–220 bp upstream of the transcription start site of the *B* gene, resulted in a decrease of expression levels and alterations in temporal specificity. The complex behavior of this region could best be explained in terms of it having three distinct functional properties, acting as a general activator, an early repressor, and a late activator. Lastly, region A2, a 35 bp sequence located 140–175 bp upstream

of the transcription start site of the *B* gene, was shown to have a general activator function; in contrast to region A1, mutations in this region did not result in altered temporal expression.

To isolate *trans*-acting factors involved in the regulation of chorion gene expression, gel retardation assays, using regions of the chorion promoters as probes, were first carried out to define DNA elements that interact with proteins from follicular cell nuclear extracts. In a few cases, the sequence features of the element allowed an accurate prediction of the type of transcription factor capable of binding the element (Skeiky and Iatrou, 1991; Sourmeli *et al.*, 2003). In other cases, oligonucleotides encompassing the elements were used to screen expression libaries from choriogenic follicles to isolate interacting factors (Kafatos *et al.*, 1995). This strategy was used in order to identify binding factors in early, early-middle, and late chorion gene promoters (Skeiky and Iatrou, 1991; Kafatos *et al.*, 1995; Sourmeli *et al.*, 2003).

1.3.4.1.3.2. Early chorion gene regulators Bandshift assays, in combination with recognition by specific antibodies, have revealed that a CAAT/enhancer binding protein (C/EBP)-like transcription factor may be an important regulator of early chorion gene expression (Sourmeli *et al.*, 2003). However, although C/EBP binding sites are more prevalent in early chorion gene promoters, such sites also occur in the chorion gene promoters of all developmental specificities. The C/EBP-like binding activity is also pronounced in nuclear extracts from early to middle choriogenic follicles, while its expression is reduced in late follicles. Thus, while the data indicate a predominant (positive) role for the C/EBP-like factor during the early stages of choriogenesis, other roles during the later stages of choriogenesis are also likely for this factor. It has been hypothesized that the C/EBP-like factor forms stage-specific complexes with other factors (e.g., the BmGATAβ factor, see below) during choriogenesis to direct stage-specific patterns of chorion gene expression (Sourmeli *et al.*, 2003).

1.3.4.1.3.3. Early-middle chorion gene regulators The strategy of screening a choriogenic follicular library with probes corresponding to binding elements in the early-middle chorion gene promoter has resulted in the isolation of five classes of cDNAs, BmMCBP1–5, which encode putative regulatory factors (Kafatos *et al.*, 1995). Of these factors, BmMCBP1–4 were found to bind the temporal regulatory region A1 (see previous section), while BmMCBP5 bound immediately upstream of the general activator region A2.

BmMCBP2, BmMCBP3, and BmMCBP5 each possess HMG-box (nucleic acid binding) regions; in addition, BmMCBP2 is characterized by a cysteine-rich region that resembles the zinc binding domain of the Trithorax (TRX) factor of *Drosophila*. BmMCBP4 has a central region that is homologous to the yeast SNF2 transcriptional activator. Finally, BmMCBP1 does not show significant homology to any transcription factors or other DNA binding proteins (Kafatos *et al.*, 1995).

In *Drosophila*, the CF1 factor was isolated by its capacity to bind the essential TCACGT element in chorion gene promoters (Shea *et al.*, 1990). Since the TCACGT element is also a prominent feature of all but the early *Bombyx* chorion gene promoters, it may be bound by the *Bombyx* homolog of CF1, BmCF1. BmCF1, which corresponds to the *Bombyx* homolog of USP, has been cloned (Tzertzinis *et al.*, 1994) and the expression pattern of its mRNA was studied during follicle development (Swevers *et al.*, 1995). The mRNA for BmCF1/USP is abundant in vitellogenic follicles, but its expression is down-regulated at the beginning of choriogenesis. Because data regarding the accumulation of the BmCF1/USP protein during oogenesis have not been reported, the role of BmCF1/USP in the control of chorion gene expression remains undetermined.

1.3.4.1.3.4. Late chorion gene regulators Gel retardation analysis using nuclear extracts of follicular cells resulted in the definition of two important binding sites in the common promoter region of one of the late gene pairs, HcA/B.12 (Skeiky and Iatrou, 1991). The DNA-binding proteins that bind these sites were designated *Bombyx* chorion factor I (BCFI; not to be confused with BmCF1/USP), and BCFII. BCFI has been considered to be the major determinant of late chorion gene expression, since binding of this factor to the late promoter region is prerequisite to the binding of BCFII and the formation of higher order complexes on the late promoters and, presumably, transcriptional activation (Skeiky and Iatrou, 1991). Both BCFI and BCFII factors have been cloned: BCFI corresponds to the BmGATAβ protein, a member of the GATA family of zinc finger motif-containing transcription factors (Drevet *et al.*, 1994), while BCFII has been shown recently to correspond to a C/EBP-like transcription factor (Sourmeli, 2004).

BmGATAβ transcription is initiated during late vitellogenesis (stage "−6"), consistent with the postulated role of the encoded protein as a major regulator of choriogenesis. Regulation of *BmGATAβ* gene expression is complex and occurs both post-transcriptionally and posttranslationally (Skeiky *et al.*, 1994; Drevet *et al.*, 1995) (**Figure 20**). Three

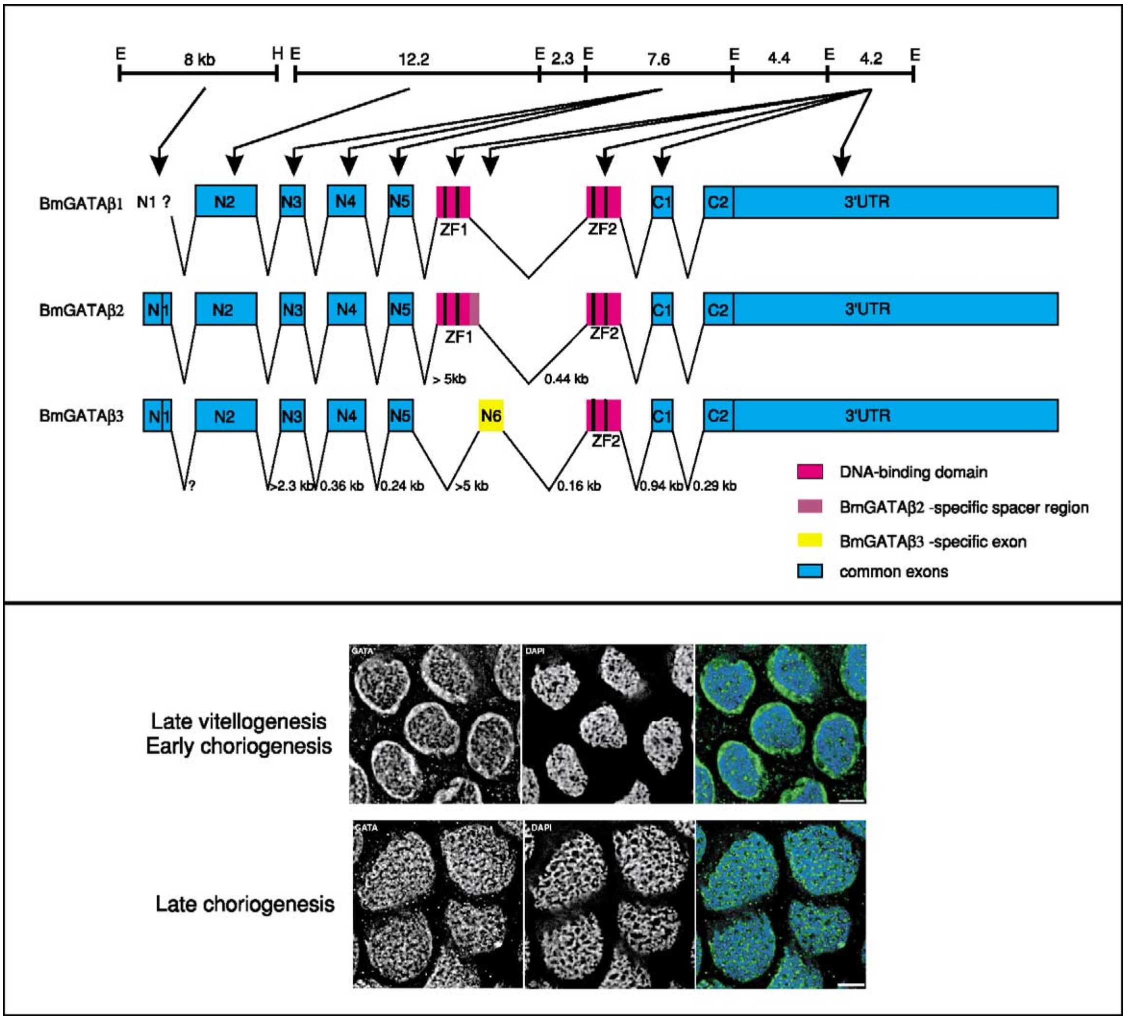

Figure 20 BmGATAβ transcription factors in *Bombyx mori*: structural features and subcellular localization in the cells of the follicular epithelium. Upper panel: Structure of the BmGATAβ gene and of the three major mRNA isoforms (β1, β2, and β3). The BmGATAβ gene consists of 10 exons, of which 9 exons could be located in a single contiguous DNA fragment that was assembled from overlapping genomic clones. The 10th exon, containing the N-terminal part of the β2 and β3 isoforms, belongs to a genomic clone that is not contiguous with the other genomic clones. E and H correspond to *Eco*RI and *Hin*dIII restriction sites, respectively, and the sizes of restriction fragments are indicated in kb. The positions of the exons of the BmGATAβ isoforms in the genomic DNA fragments are also indicated. The two exons that correspond to the N-terminal and C-terminal zinc fingers of the DNA-binding domain are in pink while the exons encoding protein regions N-terminal or C-terminal to the DNA-binding domain (N1-5 and C1-2, respectively) are in blue. In the BmGATAβ3 isoform, the exon of the first Zn finger is replaced by a unique sequence that is encoded by exon N6 (in yellow). Note that BmGATAβ1 and β2 isoforms differ by the spacing between the two zinc fingers (purple) and that the N-terminus of BmGATAβ1 is unknown. If known, the sizes of the introns that separate the different exons are indicated. Lower panel: Immunocytochemical localization of BmGATAβ protein in the follicular epithelial cells of ovarian follicles (Lunke, 2000). Shown is staining of follicular epithelia from late vitellogenic/early choriogenic follicles (top) and of follicular epithelia from late choriogenic follicles (bottom). Epithelia were treated with BmGATAβ antibody to localize BmGATAβ protein (left) or DAPI to stain nuclei (middle). At the right is shown an overlay of the left and middle images. Note that in late vitellogenic and early choriogenic follicles, BmGATAβ protein has both nuclear and perinuclear localization. In late follicles, however, BmGATAβ staining is exclusively nuclear. (Lower panel: Reprinted with permission from Swevers, L., Iatrou, K., **2003**. The ecdysone regulatory cascade and ovarian development in lepidopteran insects: insights from the silkmoth paradigm. *Insect Biochem. Mol. Biol. 33*, 1285–1297; © Elsevier.)

major BmGATAβ mRNA isoforms are generated that differ in the organization of their DNA binding domains: BmGATAβ1 and BmGATAβ2 differ by the spacing between their zinc fingers while BmGATAβ3 has the N-terminal zinc finger replaced by a new domain (Drevet *et al.*, 1995). Because the zinc fingers of GATA transcription factors can have distinct functions in DNA binding and protein interaction (Omichinsky *et al.*, 1993; Whyatt *et al.*, 1993; Fox *et al.*, 1999), the different isoforms are probably involved in the regulation of different sets of target genes. BmGATAβ2 seems to be the most

likely candidate to represent BCFI and regulate late chorion gene expression, because its expression is gonad-specific and its transcripts accumulate in ovarian follicular cells preferentially during late choriogenesis. By contrast, BmGATAβ1 and β3 have more ubiquitous expression patterns (Drevet *et al.*, 1995), and may thus regulate gene expression in many different cell types.

The function of BCFI was also found to be regulated by posttranslational modification. Bandshift assays, using cytoplasmic and nuclear extracts of follicular cells, showed that BCFI remains predominantly in the cytoplasm of the follicular cells during early and middle choriogenesis, while during late choriogenesis, the GATA element (the late chorion promoter binding sequence for BCFI) binding activity is more concentrated in nuclear extracts (Skeiky *et al.*, 1994). Furthermore, the distribution between cytoplasm and nucleus and the DNA binding specificity of BCFI were shown to be dependent of the phosphorylation status of this factor. However, immunocytochemistry experiments using an antibody that recognizes all BmGATAβ isoforms revealed that the BmGATAβ protein is present in the nuclei of follicular cells at all stages of choriogenesis, although cytoplasmic staining could also be observed in the cytoplasm of follicular cells of early and middle choriogenic follicles (**Figure 20**; Lunke, 2000; Swevers and Iatrou, 2003). A possible explanation may be that, of the existing multiple BmGATAβ isoforms, only one corresponds to BCFI and is involved in late chorion gene expression. While BCFI undergoes stage-specific nucleocytoplasmic shuttling, other isoforms may have a constitutive nuclear localization (Lunke, 2000) and be involved in the regulation of the expression of other target genes.

Because BmGATAβ binding sites (GATA elements) and C/EBP binding elements are present in all chorion gene promoters, and variable forms of the BmGATAβ and C/EBP-like factors accumulate in the nuclei of the cells of the follicular epithelium with different temporal specificities, it has been also proposed that the regulation of chorion gene batteries of different temporal specificities is achieved by the accumulation of different types of heteromeric complexes that contain stage-specific combinations of the C/EBP-like and BmGATAβ factors (Sourmeli *et al.*, 2003). A complete understanding of the precise relationships among the various BmGATAβ isoforms, C/EBP proteins, and BCFI and BCFII-type factors, will require the availability and use of factor (and isoform)-specific antibodies in immunocytochemistry and gel retardation assays.

1.3.5. Ovulation and Egg Activation

Completion of choriogenesis is followed by ovulation. During ovulation, the layer of follicle cells is removed from the mature egg. The mature egg is subsequently squeezed out of the ovary into the lateral oviduct (Bloch Qazi *et al.*, 2003).

In *Drosophila* and other insects, ovulation is stimulated by mating and, specifically by sperm and some male accessory gland proteins (Heifetz *et al.*, 2000, 2001). Through a positive feedback mechanism, increased ovulation results in the stimulation of oogenic progression of follicles. The coupling of both processes ensures that high numbers of mature oocytes are produced and high numbers of fertilized eggs are deposited (Spradling, 1993).

After ovulation, egg activation is initiated, when the egg undergoes hydration in the oviduct (Heifetz *et al.*, 2001). Features of egg activation include reinitiation of meiotic divisions (relief of arrest at metaphase I), impermeabilization of the egg coverings to small solutes (through crosslinking of the vitelline membrane and chorion) and initiation of translation (Page and Orr-Weaver, 1997; Chen *et al.*, 2000; Bloch Qazi *et al.*, 2003). All these changes will prepare the egg for subsequent embryogenesis, should fertilization occur in the uterus (Bloch Qazi *et al.*, 2003). In *Drosophila* and many other insects, therefore, egg activation occurs independently of fertilization.

While the mature egg is activated in the oviduct, little is known about the fate of the follicular epithelium that was removed from the mature egg at ovulation. Most likely, these cells undergo necrosis or apoptosis and their remnants are removed by phagocytosis.

1.3.6. Conclusions and Perspectives

From the small number of insects in which oogenesis has been studied in sufficient detail, it is clear that considerable divergence exists in the regulation of oogenesis between different insects, e.g., the variety in the hormonal mechanisms that are involved in the control of vitellogenesis (Section 1.3.3.1). In some aspects, however, remarkable conservation can occur, as illustrated by the fact that lepidopteran chorion genes can become expressed with correct temporal and spatial specificity in transgenic *Drosophila* (Section 1.3.4.1.1.2). Presumably, the evidence related to the variety of control mechanisms that operate during insect oogenesis will increase even more, should oogenesis be studied in detail in more insect species. To have a more thorough understanding of the process of oogenesis in insects, many more models are therefore needed.

In this regard, it should be also noted that the insects that have been studied in detail thus far belong mainly to two orders, the Lepidoptera and the Diptera. Moreover, from these model insects, by far the greatest wealth of information is derived from the fruit fly, *D. melanogaster*. This is due to the fact that the methods of genetic analysis are very advanced in the fly and that *Drosophila* has functioned as a model not only for insects but, also, for many other multicellular eukaryotes, including humans.

Because methods of genetic analysis have not been used in other insects until very recently, data regarding the *in vivo* function of oogenesis-related factors in other insect species are lacking. Thus, for *B. mori*, only one report exists in the literature regarding the temporal specificity of chorion gene promoters after introduction of artificial promoter-reporter constructs into the cells of the follicular epithelia by the biolistic method (Kravariti *et al.*, 2001). In this study, a small 5′-flanking region of the 6F6 early gene and the small intergenic region of the late HcA/B.12 gene pair were shown to be able to direct expression of the reporter gene in the follicular epithelia with correct temporal specificity.

Recently, however, genetic transformation of non-drosophilid insects by transposable elements has become possible in a number of other dipteran insects, including *A. aegypti*, and the lepidopteran *B. mori* (Kidwell and Wattam, 1998; Tamura *et al.*, 2000; Horn and Wimmer, 2000; Handler, 2001; Atkinson, 2002). In addition, a technique for gene targeting in the silkmoth has been developed through the use of baculovirus vectors (Yamao *et al.*, 1999). Pantropic retroviral vectors and sindbis viruses are also regarded as promising tools for foreign gene delivery in somatic insect tissues (Jordan *et al.*, 1998; Foy *et al.*, 2004). Therefore, the availability of genetic transformation techniques for additional model insects will allow the *in vivo* functional testing of the involvement of particular factors that were identified by *in vitro* methods, in oogenesis. As long as these types of experiments have not been carried out, the function of the identified factors (e.g., in *Aedes* or in *Bombyx*) remains speculative.

Another recent development is the application of the technique of RNA interference (RNAi) to knock down the function of genes in cells and tissues (Hannon, 2002). RNAi is based on the introduction into the cells of double-stranded RNA, which becomes processed by the endogenous cytoplasmic enzyme Dicer into small (20–22 nt) double-stranded RNA species known as "small interfering RNAs" (siRNAs). siRNAs subsequently become integrated into a multiprotein complex known as the RNA-induced silencing complex (RISC), where they function as guide RNAs to target homologous mRNAs for cleavage and degradation (Dykxhoorn *et al.*, 2003). The advantage of the technique of RNAi is that it can be easily applied to knock down gene expression and that no extensive knowledge of the genetic make-up of a particular organism is required. The technique of RNAi has already been applied successfully in several insect species (Marie *et al.*, 1999; Lam and Thummel, 2000; Quan *et al.*, 2002; Bettencourt *et al.*, 2002; Blandin *et al.*, 2002; Rajagopal *et al.*, 2002; Valdes *et al.*, 2003; Uhlirova *et al.*, 2003), therefore it holds great promise for the genetic analysis of gene function in insects, in general, including oogenesis.

1.4 Spermatogenesis

R Renkawitz-Pohl and L Hempel, Philipps-University, Marburg, Germany
M Hollmann and M A Schäfer, Universität Kassel, Kassel, Germany

1.4.1. Introduction

Spermatogenesis is a highly specialized process of cellular differentiation resulting in the formation of functional spermatozoa for successful reproduction. In principle, the process of spermatogenesis is well conserved in all sexually proliferating organisms, although the size and shape of the mature sperm vary considerably among different species. Many details are comparable between mammals and *Drosophila* making the fly a very good model system to study fertility defects. *Drosophila* germ cells, like those of mammals, are set aside early in embryonic development and migrate through the primordium of the hindgut into the interior of the embryo where they join the somatic parts of the embryonic gonads (review: Zhao and Garbers, 2002). At the end of the third larval instar and the onset of pupariation, the first germ cells enter meiosis (**Figure 1**).

Spermatogenesis is a continuous process during adult life and, thus, the adult testes contain all stages from stem cells to mature sperm (**Figure 1**). As in mammals, the germ cells develop in close contact with somatic cells, in this case the cyst cells, which are of mesodermal origin. At the very tip of the testis tube, the so-called hub is formed by somatic support cells (asterisk in **Figure 1**) to which the germline stem cells (GSCs) and the cyst cell progenitors (somatic stem cells, SSCs) are physically connected. In close contact to the hub, both stem cell types divide asymmetrically depending on the JAK-STAT signaling pathway (see Section 1.4.3.1 for details). One daughter cell remains connected to the hub and maintains stem cell characteristics. The other daughter cell becomes disconnected from the hub and enters the differentiation process. This germ cell, now called spermatogonium, is surrounded by two cyst cells, thus forming a cyst in which the germ cell undergoes four mitotic divisions, meiosis, and sperm morphogenesis until individualization (see **Figure 3** for an overview).

The ultrastructure and cytology of *Drosophila melanogaster* spermatogenesis has been extensively reviewed by Fuller (1993). This complex differentiation process from round cells to the highly specialized structure of spermatozoa is controlled by a large number of genes (up to 1500) affecting spermatogenesis, which is reflected in the large number of male sterile mutants (reviews: Lindsley and Tokuyasu, 1980; Hackstein *et al.*, 2000). The focus here is on the recent advances in understanding the molecular basis for the dramatic changes in

cell morphology during germ cell development starting with the asymmetric division of stem cells into a stem cell and a spermatogonium as the entry point to germ cell differentiation. Control of mitotic proliferation and entry into meiosis are discussed and various aspects of sperm morphogenesis highlighted, such as the formation of the axoneme and the mitochondrial derivative, the Nebenkern. Then the importance of cell interactions during the process is discussed (**Figure 4**), and finally transcriptional and translational control mechanisms during meiotic prophase, and their relevance for sperm morphogenesis (**Figure 3**).

1.4.2. Morphology and Development

At the cellular blastoderm stage of embryogenesis, the somatic cells and the primordial germ cells (PGCs), visible as pole cells, are separated. During gastrulation, pole cells migrate into a pocket of the posterior endoderm primordium through which they migrate into the interior of the embryo. This invasion and the guided migration together with mesodermal cells is followed by aggregation of both cell types to form the gonad. It has been reently shown that the receptor tyrosine kinase Torso (Tor) activates both signal transducer and activator of transcription (STAT) and Ras, a monomeric GTPase, during the early phase of PGC development, and that coactivation of STAT and Ras is required for invasive migration (Li *et al.*, 2003). Then germ cells comigrate with cells of mesodermal origin to the abdominal segment A5, which surround the germ cells and give rise to the gonad sheath. The *fear of intimacy* (*foi*) gene is expressed in the gonadal mesoderm and encodes a transmembrane protein. Foi and E-cadherin encoded by the *shotgun* (*shg*) locus are similarly required for gonad coalescence, the final step in gonad formation (Jenkins *et al.*, 2003; Van Doren *et al.*, 2003). In *foi* mutants, E-cadherin levels are dramatically decreased indicating that Foi is a positive modulator of E-cadherin expression or function. Thus, Foi is needed to maintain high levels of E-cadherin and thereby proper cell adhesion for gonad formation.

Already during gonad formation, sex-specific effects can be observed in the somatic part of the gonad and the germline. During gonad coalescence a group of cells, termed the male-specific somatic gonadal precursors (msSGPs), is specified. These cells express Sox100B, a *Drosophila* homolog of Sox9, which is an essential transcription factor for testis development in mammals. The msSGPs are incorporated into the male gonad only; in the female sex, they are eliminated by sex-specific apoptosis leading to a difference in gonad morphology between the sexes (DeFalco *et al.*, 2003). Furthermore, even though both sexes start out with the same number of pole cells formed, the gonads incorporate a sex-specific number of germ cells. Male gonads contain 14,2 germ cells, on average, compared to 12,2 in female gonads (Poirié *et al.*, 1995).

In abdominal segment A8, the genital disc is established. This differentiates during metamorphosis into the genital ducts and their accessory structures such as seminal vesicles and accessory glands, which are also called paragonia (see Hartenstein, 1993 and **Figure 1** for an overview of the male reproductive tract). Sex determination in *Drosophila* has been well studied and shown to be a cell autonomous process in somatic cells (review: Lalli *et al.*, 2003; see also **Chapters 1.1** and **1.7**). The germ cells are determined in the gonads to enter spermatogenesis or oogenesis. XX germ cells are in contact with XX somatic cells of the gonad which leads to repression of male-specific gene transcription by a short-range signal (Heller and Steinmann-Zwicky, 1998). In XY germ cells, cell autonomous and somatic signals lead to male-specific gene expression and spermatogenesis (Janzer and Steinmann-Zwicky, 2001).

1.4.2.1. Spermatogonia

Spermatogonia go through a mitotic amplification phase with incomplete cytokinesis such that the germ cells remain interconnected and, thus, establish cytoplasmic bridges with ring canals and fusomes. Cessation of mitoses and transition into meiotic prophase is dependent upon the genes *bag of marbles* (*bam*) and *benign gonial cell neoplasm* (*bgcn*) in the germ cells and transforming the growth factor-β (TGF-β) signaling from the cyst cells (Gönczy *et al.*, 1997; review: Fuller, 1998). The molecular analysis revealed that Bgcn is related to DexH-box proteins and may be involved in translational control (Ohlstein *et al.*, 2000). Bam is localized in the cytoplasm, but no further clues to its function exist (McKearin and Spradling, 1990; McKearin and Ohlstein, 1995). The genes *bam* and *bgcn* also play a role in oogenesis. There they are essential for the distinction between stem cell and oogonium during asymmetric stem cell division, as discussed in Section 1.4.3.2. (review: Deng and Lin, 2001; see **Chapter 1.2**).

1.4.2.2. Spermatocytes

After four mitotic divisions, the cells within the cyst enter meiosis as primary spermatocytes (**Figure 1a**) and remain in the G2 phase of the cell cycle for ~3.5

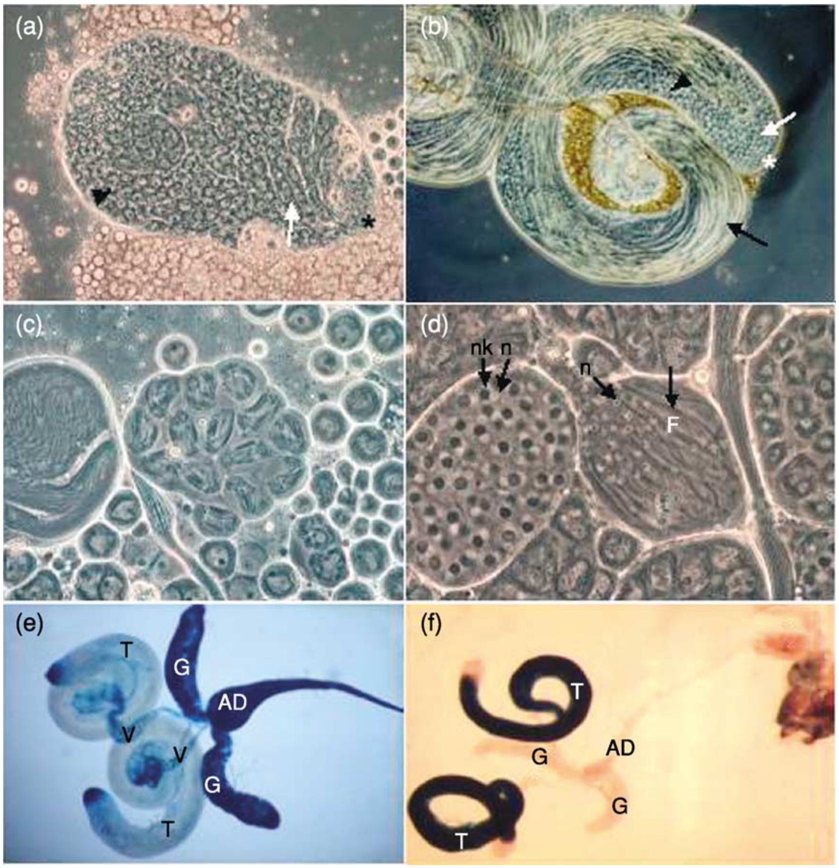

Figure 1 Stages of spermatogenesis in testes of late third instar larvae and adult males. (a) Testis anlage of a larva showing the hub and stem cell region at the apex (asterisk), a cyst with spermatogonia (white arrow), and a cyst with primary spermatocytes (black arrowhead). (b) Testis of an adult male showing the apical tip with hub and stem cells (asterisk), spermatogonia (white arrow), spermatocytes (arrowhead), and elongated spermatids (black arrow). (c) The cyst shows synchronous meiotic divisions. (d) The left cyst shows a Nebenkern stage shortly after the second meiotic division. In the phase contrast optics the nucleus (n) appears light, the Nebenkern (nk) dark. The right cyst contains young spermatids with a round nucleus (n) and an elongating flagellum (F). (e) β1-LacZ reporter gene expression in the male reproductive tract (Wβ1K-carrying transgenic line; Buttgereit and Renkawitz-Pohl, 1993). Within the testes (T), stem cells and spermatogonia express β-galactosidase. In addition, β-galactosidase expression is also observed in the *vas deferens* (V), in accessory glands (G), and in the ejaculatory duct (AD). (f) β2-LacZ reporter gene expression in the male reproductive tract (Michiels *et al.*, 1989).

days (Lindsley and Tokuyasu, 1980). This stage is characterized by extensive transcription, leading to a 25-fold size increase of the nuclei, and by the formation of lampbrush loops from the Y chromosome, which are essential for male fertility (review: Hackstein and Hochstenbach, 1995). At least some of these Y chromosome fertility genes encode dynein subunits (see Section 1.4.2.4.1). Meiotic arrest mutants show developmental arrest at the transition from G2 to meiosis I as they control the accumulation of Twine (Twe), a Cdc25 homolog (White-Cooper *et al.*, 1998). The meiotic arrest mutants – *always early* (*aly*), *cannonball* (*can*), *meiotic arrest* (*mia*), *cookie monster* (*comr*), and *spermatocyte arrest* (*sa*) – fall into two classes (Fuller, 1998; White-Cooper *et al.*, 1998; Jiang and White-Cooper, 2003). Aly and Comr are proposed to belong to chromatin remodeling complexes, while Can, Mia, and Sa form the second class. At least for Can, it has been shown that it interacts directly with the transcription initation complex of sperm differentiation genes, which will be discussed in detail below (for a model, see Jiang and White-Cooper, 2003).

1.4.2.3. Meiosis

Clearly, many features are common between mitosis and male as well as female meiosis (see **Chapter 1.2**). A peculiar feature of *Drosophila* male meiosis, however, is the lack of synaptonemal complex formation with the consequence that meiotic recombination does not occur in male germ cells. After the extended meiotic prophase I, all further stages of the meiotic divisions proceed rapidly, following induction by specific pathways and appropriate actions of cell cycle regulators such as Twe, a Cdc25-type phosphatase, and Boule (Bol), an RNA binding protein.

Both are essential for G2/M transition and Boule controls Twine translation (Maines and Wasserman, 1999). The meiotic spindle has to be assembled and, later, the contractile ring must assemble in order for cytokinesis to take place (review: Maines and Wasserman, 1998). The first 16 spermatocytes within one cyst enter the meiotic divisions at the white prepupal stage. During the first meiotic division the two nuclear membranes remain until telophase, then they disintegrate and stepwise reform. For the rapidly ensuing second division the situation is less well analyzed but seems to be similar (Tates, 1971; Church and Lin, 1982). In both divisions, mitochondria line up and are distributed equally among the daughter cells (Fuller, 1993). Furthermore, as in every meiosis, chromosome segregation has to be tightly controlled. Recently, the *Drosophila* mutants *fusolo* and *solofuso* have been analyzed in male meiosis. Homozygous mutants are severely defective in chromosome segregation and produce secondary spermatocytes that are devoid of chromosomes (Bucciarelli *et al*., 2003). The occurrence of these secondary spermatocytes without chromosomes shows that spindle formation and cytokinesis are independent of the presence of chromosomes (Bucciarelli *et al*., 2003). From the study of mutants in specific genes there is clear evidence that formation of the contractile ring constriction and its disassembly require different genes (review: Giansanti *et al*., 2001).

Several genes have been identified that interfere with one or several aspects of meiosis, but a general network of control has not emerged yet. Mutations in the genes – *sa*, *can*, *aly*, and *mia* – lead to meiotic arrest in cell cycle progression and spermiogenesis. Lin *et al*. (1996) therefore suggested the existence of a control point that may serve to coordinate the male meiotic cell cycle with the spermatid differentiation program. Time-lapse microscopy revealed the existence of a spindle checkpoint in male meiosis, where a large number of misaligned chromosomes or severe disruption of the spindle leads to delays in the entry into anaphase (Rebollo and González, 2000). As demonstrated by the phenotype of mutants in *pelota (pelo),* this gene is involved in spindle formation and nuclear envelope modification but not in chromatin condensation, which proves that various aspects of meiosis are controlled by different genes (Eberhart and Wasserman, 1995). During germ cell divisions, cytokinesis is incomplete, resulting in clusters of cells with stable intercellular bridges which interconnect mitotically or meiotically related germ cells. These stable intercellular bridges are called ring canals and the total set of ring canals between the germ cells in one cyst is termed the fusome (see **Chapter 1.2**). In males, the cohort of cells remains interconnected until sperm individualization. Actin organization and the formation of intercellular bridges are different in the male and female germline (Hime *et al*., 1996). Mature ring canal walls in males lack actin, but contain three septins (Pnut, Sep1, and Sep2) and anillin. Anillin and septins are missing in ovarian ring canals, in which filamentous actin is a major component. A mutation in *four wheel drive (fwd)*, a PI4-kinase, affects the formation of these intercellular bridges during meiosis. This PI4-kinase is required during cytokinesis for tyrosine phosphorylation in the cleavage furrow and organization of actin filaments in the constricting contractile ring. Loss of PI4-kinase activity leads to unstable cleavage furrows and to fusion of daughter cells resulting in multinucleate spermatids (Brill *et al*., 2000); consequently, ring canals are not established.

Genes of general importance may also have a specific function in spermatogenesis. The gene *fumble (fbl)* encodes a pantothenate kinase homolog that is required for mitosis and meiosis during spermatogenesis and affects spindle organization, chromosome segregation, and contractile ring formation. Since it localizes to areas of membrane deposition, its function could be related to synthesis and redistribution of membranous material (Afshar *et al*., 2001). Centrosomes contain the protein Centrosomin (Cnn) and organize the spindle assembly. After male meiosis the centriole is transformed into the sperm basal body. A novel isoform of Cnn that is expressed during spermatogenesis is essential for spindle organization and for the organization of the sperm axoneme (Li *et al*., 1998). During mitotic spindle assembly, the kinase aurora-A interacts with the C-terminal sequence of Cnn and thereby regulates centrosome assembly. The N-terminal half of Cnn then interacts with γ-tubulin. Thus, this kinase controls the ability of Cnn to target and/or anchor γ-tubulin to the centrosome (Terada *et al*., 2003).

During spermatogenesis several special formations of the endoplasmic reticulum and the Golgi can be observed. When spermatocytes enter meiosis they develop parafusorial membranes as well as astral membranes that surround the nucleus on the outside of its double membrane. During spermiogenesis the Golgi forms the acrosome which is necessary for sperm–egg recognition and interaction on the sperm head, and an acrosomal sheath generated from the endoplasmic reticulum (ER) extends along the elongating sperm tail (Lindsley and Tokuyasu, 1980; Fuller, 1993). Thus, it is not surprising that mutations in many genes, with roles in ER formation or processes related to it, would lead to a male

sterile phenotype during spermatogenesis. Syntaxin 5 (Syx5) is a Golgi-localized soluble NSF attachment receptor (SNARE) protein shown to be required for ER–Golgi vesicle traffic. Homozygous flies for a hypomorphic allele are male sterile. This results both from the failure of germ cells to complete cytokinesis and from defects in spermatid elongation and maturation. Thus, during spermatogenesis, Syx5 is required for cytokinesis and for spermatid differentiation, which demonstrates the importance of proper establishment of the Golgi apparatus and its special derivatives during spermatogenesis (Xu *et al.*, 2002). Similarly, mutations in *four way stops* (*fws*) cause dramatic alterations in cell morphology related to Golgi architecture, including disruption of the formation and/or stability of the Golgi-based spermatid acroblast. The *fws* gene encodes the *Drosophila* Cog5 homolog, a subunit of the multisubunit complex COG (conserved oligomeric Golgi). This allows the hypothesis that vesicle traffic is essential during sperm morphogenesis (Farkas *et al.*, 2003). A testis-specific vesicle-associated membrane protein-associated protein (VAP)-like protein, Farinelli (Fan), has been identified, which also associates with derivatives of the ER during various stages of spermatogenesis. Mutations in *fan* result in individualization defects, which could be related to defective transport processes (U. Renner, M. Hollmann, and M.A. Schäfer, in preparation).

1.4.2.4. Sperm Morphogenesis

1.4.2.4.1. Axoneme: β2-tubulin and dynein Motility of the sperm is dependent on the axoneme, which is composed of nine outer microtubule doublets and two inner microtubuli as well as a number of other proteins. The axoneme structure is highly conserved in cilia and flagella from protists to mammals, suggesting a common assembly mechanism. The cylinder of nine doublet microtubules is initiated from the triple microtubules of the basal body, while the inner two microtubules are formed separately. The microtubules are characterized by the presence of the testis-specific isotype β2-tubulin (for a review on the genetics of tubulin genes, see Fuller, 1993).

The β2-tubulin isotype shares a highly conserved C-terminal sequence motif with β-tubulin isotypes from the axoneme of other species. This region is called the axoneme-specific sequence motif (Nielsen *et al.*, 2001). Testing of this motif in the context of the β1-tubulin isotype in transgenic flies showed, in particular, that this β2-tubulin isotype is essential for the specification of the central pair of microtubules in the axoneme (Nielsen *et al.*, 2001). It has been suggested that cooperativity in the function of internal β2-tubulin sequences is needed for the assembly of the exceptionally long *Drosophila* axoneme (Nielsen and Raff, 2002).

Dyneins are the major motor proteins responsible for sperm motility. It has first been shown by Goldstein *et al.* (1982) that the loss of the Y chromosome fertility factors Kl-3 and Kl-5 causes the loss of the outer arms on the microtubule doublets in the axoneme and the lack of three large proteins, presumably dynein heavy chains. Sequence analysis of one of the Y chromosome fertility factor genes, *kl-5* in *D. melanogaster* (Gepner and Hays, 1993) and *threads* in *D. hydei* (Kurek *et al.*, 1998), indeed showed that a dynein heavy chain β-polypeptide is encoded by a giant transcription unit of a Y chromosome fertility factor in both species. Furthermore, it was recently shown that the fertility factor genes *kl-2* and *kl-3* of the *D. melanogaster* Y chromosome encode a β- and a γ-dynein heavy chain, respectively (Carvalho *et al.*, 2000).

In addition to motility, the sperm tail needs flexible stability to allow movement but prevent breakage of the tail. In mammalian systems, this seems to be achieved by nine large structures around the axoneme, the outer dense fibers (ODFs) (Baccetti *et al.*, 1973; Baltz *et al.*, 1990; Haidl *et al.*, 1991). They contain specific ODF proteins (Burfeind and Hoyer-Fender, 1991; Morales *et al.*, 1994), which were identified using the *Drosophila Mst87F* gene as probe, a Male-specific transcript (Mst) at polytene band 87F. Thus, it is proposed that *Mst87F* and related proteins (see below) are the major components of the satellites on the outside of the outer microtubule doublets in *Drosophila* (Kuhn *et al.*, 1988; Schäfer *et al.*, 1995), which represent the ODF homologous structures in the fly flagellum (Baccetti *et al.*, 1973).

1.4.2.4.2. Mitochondrial derivatives Sections through the sperm tail reveal the axoneme and, along the axoneme, the two mitochondrial derivatives, the major and minor mitochondrial derivative, which are needed to supply the axoneme with ATP for motility. These mitochondrial derivatives originate from the fused mitochondria. Immediately after meiosis, they form an electron dense structure next to the nucleus (see **Figure 1d**). Because of its nucleus-like shape the structure at this stage was named Nebenkern (**Figure 1d**). The two mitochondrial derivatives are wrapped into each other during the onion stage of the Nebenkern (for morphological details see review by Lindsley and Tokuyasu, 1980). During spermatid development this sphere, with a diameter of 7 μm, changes to a cylinder, 1.8 mm in length. First, the mitochondrial derivatives

unwrap into one major and one minor derivative, and then these huge mitochondria elongate along the axoneme. In elongated spermatids, a basic protein termed Don Juan (DJ) is found in the mitochondrial derivatives. This protein may be involved in the final steps of mitochondrial differentiation (Santel *et al.*, 1998), in addition to its proposed function in the nucleus (see Section 1.4.2.4.3). As there are no mutants available so far, the function of DJ in the mitochondrial derivatives remains to be clarified.

At a molecular level, the function of the gene *fuzzy onion* (*fzo*) gave a first insight into the mechanism of Nebenkern development. This gene encodes a GTPase that is expressed in a stage-specific fashion and is essential for fusion of the mitochondria (Hales and Fuller, 1997). This GTPase belongs to the well-conserved mitofusin GTPases, of which *Drosophila* contains two isoforms: the specific form for Nebenkern morphogenesis and a ubiquitously expressed isoform named *Drosophila* Mitofusion (Mfn) (Santel and Fuller, 2001; Hwa *et al.*, 2002 and literature cited therein). Its homolog in *Sacharomyces cerevisiae*, yFzo1, has been studied at the functional level and shown to be required for mitochondrial fusion after mating and also for the continuously ongoing mitochondrial fusion events that maintain the dynamic network of mitochondrial filaments in vegetatively growing yeast. Recently, the human homologs Mfn1 and Mfn2 have also been characterized (Santel *et al.*, 2003 and literature cited therein).

1.4.2.4.3. Chromatin condensation and nuclear shaping In mammals, it is well known that the somatic set of histone proteins is modified during meiotic prophase (reviews: Hecht, 1998; Braun, 2001). After meiosis, histones are replaced first by the transition proteins (TP1 and TP2), which are largely redundant in function. TP1 is a small basic protein of 54 amino acids, while TP2 has the size of a core histone (for a review on chromosomal proteins in spermatogenesis in different animal species, see Wouters-Tyrou *et al.*, 1998). Transition proteins are then replaced by the highly basic protamines to ensure the remodeling of chromatin to the typical highly condensed and transcriptionally silent state of the mature sperm (review: Sassone-Corsi, 2002). At the level of the light microscope, the *Drosophila* spermatid nucleus is round after meiosis and then becomes a needle-like structure with highly condensed chromatin by an as yet unknown mechanism (see **Figure 2** for a detailed description of postmeiotic nuclear stages in several *Drosophila* species).

Unfortunately, little is known about the molecular processes leading to chromatin reorganization and condensation in *Drosophila*. An autosomal gene, *Mst77F*, has been identified by its male-specific transcription (Russell and Kaiser, 1993), which encodes a presumptive histone 5 belonging to the histone H1 group (Thomas, 1984). This histone H5 is involved in global transcriptional inactivation in the nucleated erythrocytes of chickens. It has been proposed to be involved in sperm chromatin condensation, but no further investigations were carried out (Russell and Kaiser, 1993). A histone-3 variant (H3.3) has been shown to be highly expressed during meiotic prophase in the male germline, where it is associated with some of the lampbrush loops. After meiosis, H3.3 associates in a nonrandom fashion with the chromatin of early spermatid nuclei but mainly colocalizes with the chromatin close to the nuclear membrane. The somatic H3 isoform, however, remains associated with the majority of the chromatin. Although this distribution is stable during the elongation phase of the nuclei, histones are undetectable by immunohistology in the nuclei of mature sperm (Akhmanova *et al.*, 1997).

In spite of histochemical evidence (Das *et al.*, 1964), it still remains an open question as to whether histones are replaced by protamine-like basic proteins. In the fly genome, six testis-specific proteasome subunits have been described. Two of them have been localized to the sperm nuclei from the elongated spermatid stage onward. It has been proposed that these nuclear proteasomes degrade histones (Ma *et al.*, 2002). Recently, a 160 kDa basic protein, RADHA, encoded by the *radha* (*rha*) gene, with a C-terminal leucine zipper has been described as a testis-specific nuclear protein. RADHA has been localized to the nuclei of primary spermatocytes, round spermatids, and elongating sperm heads (Harhangi *et al.*, 1999). Unfortunately, mutants that could help to elucidate the function of RADHA do not exist. A role as a histone replacement protein seems unlikely, however, due to its large size of 160 kDa compared to mammalian protamines of 10 kDa or less.

Another candidate for a histone replacement protein is the lysine-rich protein DJ with a molecular mass of 29 kDa and a predicted isoelectric point of 9.84 (Santel *et al.*, 1997). Its size and structural homology to histone H1 suggest that DJ may be a chromatin organizing protein. DJ is exclusively expressed in the male germline and its mRNA is under translational repression until the elongated spermatid stage (see Section 1.4.4.3). It is first detectable in spermatid nuclei at the end of nuclear transformation and, shortly after, in the mitochondrial

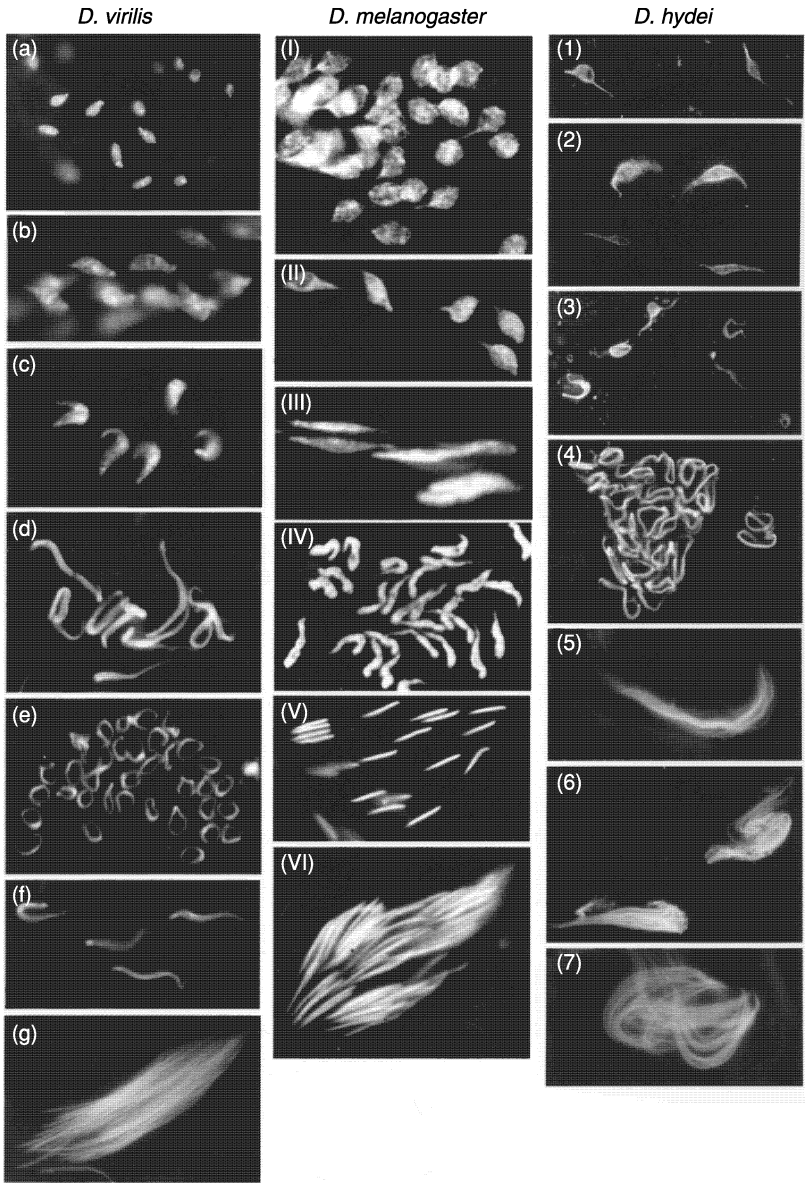

Figure 2 Chromatin condensation during spermiogenesis of *D. melanogaster, D. hydei, and D. virilis*. The panels show nuclear morphogenesis followed by Hoechst 33258 staining of DNA. (a, I, 1) The nucleus is round and the chromatin is distributed throughout the nucleus. (b, II, 2) The chromatin starts to change its distribution as the nucleus starts to elongate. (c, III, 3) The nucleus is ellipsoid and the chromatin concentrates on one side. (d, e, IV, 4, 5) The nucleus further elongates and the chromatin concentrates further. (f, V, 6) The chromatin starts to compact accompanied by further elongation of the nucleus and reduction of nuclear volume. Nuclei are already slim and the chromatin forms a needle-like structure. (g, VI, 7) The nuclei of one cyst are visible as thin and needle shaped structures shortly before individualization.

derivatives, immediately at the onset of individualization (Santel *et al*., 1998). Using immunohistological techniques, DJ is no longer detectable within the nucleus at the onset of individualization, but it cannot be excluded that the protein is not accessible to the antibodies in the highly condensed chromatin at this stage. It is very tempting to postulate that DJ transiently replaces histones, as it exhibits a nuclear localization at a stage when histones are no longer detectable. DJ may act together with DJ-like, a closely related basic protein, which is expressed at the elongated spermatid stage (L. Hempel, C. Rathke and R. Renkawitz-Pohi, in preparation). The establishment of a clear functional role for DJ and DJ-like with respect to chromatin remodeling during spermiogenesis requires the analysis of relevant mutants.

Recent studies give evidence for two true protamines in *Drosophila*. The analysis of the *Drosophila* genome sequence (Adams *et al*., 2000; Celniker *et al*., 2002) led to the identification of two genes with homology to protamines, for which testis-specific transcripts have been described (Ashburner *et al*., 1999; Andrews *et al*., 2000). When these protamines are fused to Green fluorescent protein (GFP) and analyzed in transgenic flies, they represent the major chromosomal proteins in *Drosophila* sperm (**Figure 3**; S. Jayaramaiah Raja and R. Renkawitz-Pohi, submitted). Thus, *Drosophila* sperm contain two protamines as do mammalian sperm. After fertilization and before zygote formation, the protamines have to be removed from the paternal pronucleus, and a nucleosomal configuration of the chromatin has to be established again (see **Chapter 1.6**). In the maternal effect mutant *sésame* (*ssm*), histones have no access to the paternal pronucleus suggesting that sésame is an essential component of the chromatin reorganization machinery in the male pronucleus (Loppin *et al*., 2001).

1.4.2.4.4. Individualization After the axoneme is assembled, the minor and major mitochondrial derivatives are appropriately positioned, the chromatin is tightly packed, the acrosome is established, and all other processes of sperm morphogenesis are completed, but the spermatids are still present in one bundle. As a final step of spermiogenesis, the surplus of cytoplasm needs to be removed and the 64 spermatids have to be separated, so that individual membranes encase each of the 64 mature spermatozoa. This is achieved by the so-called individualization complex (IC), which is assembled at the spermatid heads. Its assembly begins with the formation of actin cones around the nuclei, to which additional proteins are recruited (see below). The IC migrates as a cystic bulge along the sperm tail towards the tip of the tail. It removes excess cytoplasmic material by an apoptosis-based process (see below), and remodels the membranes as it moves. The complexity of the process is reflected by the large number of mutants with defects in individualization, including mutations in a Clathrin heavy

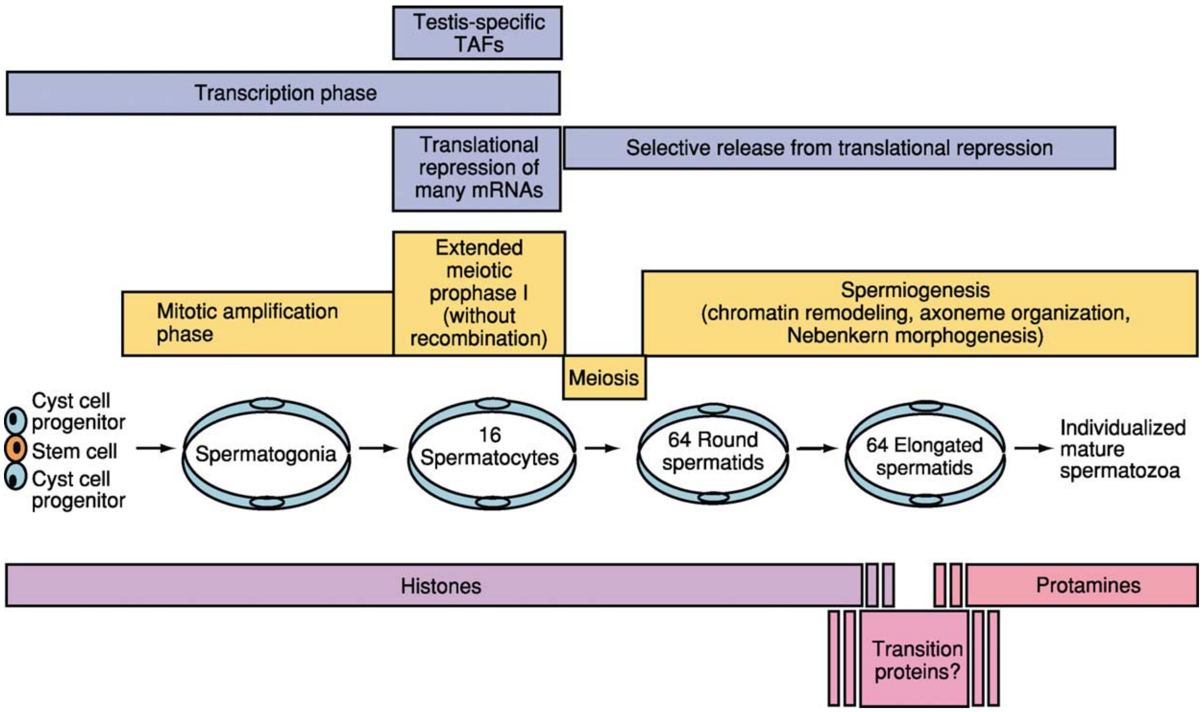

Figure 3 Major developmental and regulatory features during *D. melanogaster* spermatogenesis. The highly regulated developmental program leads from the asymmetric division of a stem cell to the spermatogonium, which is committed to sperm differentiation. Individual spermatogonia amplify enclosed by two cyst cells and enter the meiotic prophase synchronously. Primary spermatocytes are transcriptionally active with the help of stage and tissue-specific transcription initiation complexes. From this stage onward, many transcripts become translationally repressed and remain repressed until the appropriate time during sperm morphogenesis occurs. Shortly after meiosis, spermatids are characterized by a light round nucleus and an adjacent dark Nebenkern (see **Figure 1d**). The 64 spermatids mature in close association with the head and the tail cyst cell until individualization. Before meiosis the chromatin is in a nucleosomal conformation, but after meiosis histones disappear and the chromatin becomes tightly compacted, presumably through the action of basic proteins such as transition proteins and protamines, as in mammals.

chain (Chc) and a calmodulin binding protein encoded by *purity of essence* (*poe*) (Fabrizio *et al*., 1998). These have been grouped into four classes according to their phenotypic characteristics.

The moving IC structure is actin/myosin VI based. In this complex structure, myosin VI colocalizes with the actin polymerization regulatory protein cortactin and the actin-related protein 2/3 (Arp2/3) complexes as well as the actin capping protein at the front (Hicks *et al*., 1999; Rogat and Miller, 2002). The movement of the IC can be followed in *in vitro* cultures (Nogushi and Miller, 2003). Recently, it was shown that an apoptosis-like process is involved in individualization (Arama *et al*., 2003). Caspase activity is required for the translocation of individualization complexes and cytoplasm removal from the elongated spermatids. This activity is dependent on cytochrome-c-d activity, encoded by one of the two *cytochrome c* genes of *Drosophila*. Apoptotic processes must be restricted to the cytoplasmic compartment, however. This might be effected by the local action of dBruce, a giant E2 ubiquitin-conjugating enzyme, which could bind directly to caspases and degrade them (Arama *et al*., 2003).

As has been found for meiosis, control points seem to exist during sperm morphogenesis leading to similar phenotypes for a number of different mutations, which resulted in the classification of the mutants (see above and Fabrizio *et al*., 1998). For example, mutations in *ance* (angiotensin converting enzyme gene homolog) cause misalignment of nuclei, an abnormal structure of the mitochondrial derivatives, and a drastic reduction of individualization complexes. Similar phenotypes are produced by other individualization mutants (Hurst *et al*., 2003), which have not been analyzed at the molecular level as yet.

1.4.3. Cell–Cell Interactions during Spermatogenesis

The first analysis of possible interactions between the germline and somatic cells was performed by Gönczy and DiNardo (1996), who studied the behavior of the somatic cells, in agametic testes and testes containing reduced number of germ cells, using specific cell markers. Their experiments showed that the cells of the hub differentiate independently of the germ cells, whereas the cyst cells react to the absence of germ cells. Thus, although the number of cyst progenitor cells and daughter cells is often reduced in agametic testes, these cells can differentiate in the absence of germ cells. It was further demonstrated that germ cells restrict the proliferation of differentiated cyst cells, as in the absence of germline cells the number of cyst cells in old testes is significantly higher than in younger ones (Gönczy and DiNardo, 1996). The cyst cells of agametic testes incorporate BrdU, indicative of their mitotic activity, and some of them adopt a hub cell fate later on. In mutants for the actin binding protein coding genes *chickadee* (*chic*) and *diaphanous* (*dia*), the number of germ cells severely decreases during adult life. Also in these mutants, the cyst cells undergo similar alterations in the testes of adult flies after all germ cells have been eliminated. This does not happen in the larval testis anlagen, where the germ cells are still present. This indicates that persistent signaling as opposed to a signaling pulse from the germ cells to the cyst cells is necessary during the early steps of spermatogenesis.

1.4.3.1. Stem Cells and the JAK-STAT Pathway

At the tip of each testis tube, a group of nondividing somatic cells, the hub, is surrounded by the germline stem cells (GSCs, **Figure 1**). These GSCs are accompanied by somatic stem cells (SSCs). Both stem cell types are defined by their undifferentiated state and their unlimited proliferation potential. The hub cells form the so-called stem cell niche and, like the two stem cell types, they also express *piwi*, a gene that encodes a nucleoplasmic protein that is essential for the determination of the number and division rate of the germline stem cells (Lin and Spradling, 1997; Cox *et al*., 2000). The *piwi* gene is conserved even between the plant and animal kingdom (Cox *et al*., 1998), but the pathway through which it acts has not been determined as yet.

Oriented divisions of the stem cell lines generate daughter cells that remain as stem cells and daughter cells that differentiate into gonialblasts (germ cells that are committed to undergo differentiation) or cyst cells. Spindle positioning during germline stem cell division has been analyzed in detail (Yamashita *et al*., 2003). Its orientation is always perpendicular to the hub–GSC interface, which ensures that one daughter cell remains in contact with the hub, whereas the other daughter cell is displaced from the hub and, therefore, can receive signals that promote differentiation. Spindle positioning is directed by cell adhesion via *Drosophila* epithelial cadherin (E-cadherin) that is restricted to the interface between hub cells and GSCs. E-cadherin then provides a platform of binding sites for the β-catenin Armadillo (Arm), and one of the two *Drosophila* homologs of the mammalian adenomatous polyposis coli (APC2). APC2 can, in turn, orient the spindle through the microtubules and an intrinsic protein complex containing APC1 and the centrosome component Cnn. Thus, spindle orientation

plays a critical role in the mechanism that maintains the correct balance between stem cell self-renewal and initiation of differentiation throughout adult life (Yamashita *et al.*, 2003). The gonialblast that dislocates from the hub after the stem cell division is enclosed by two cyst cells that are derived from the SSCs (**Figure 3**). These cyst cells are essential for the differentiation of the blast cell and its progeny throughout spermatogenesis (see Section 1.4.3.2).

The stem cell lineage requires the function of the Janus kinase-signal transducers and activators of transcription (JAK-STAT) signaling pathway for its maintenance (Kiger *et al.*, 2001; Tulina and Matunis, 2001), a pathway that is highly conserved and involved in a variety of biological processes (review: Hou *et al.*, 2002). The JAK ligand Unpaired (Upd) is expressed in the somatic hub cells and activates the JAK-STAT pathway in the adjacent stem cell daughter by binding to the Upd receptor Domeless (Dome), which in turn activates the Janus kinase Hopscotch (Hop) and the transcription factor Stat92E (**Figure 4**). This activation causes the cell to retain its stem cell identity. Mutations in the *stat92E* gene lead to loss of stem cells after 5 days, whereas overexpression of *upd* results in more stem cells and prevention of differentiation. Interestingly, activation of *upd* also results in the generation of excess somatic stem cells, indicating that the maintenance of both stem cell populations is dependent on hub signaling (reviews: Castelli-Gair Hombria and Brown, 2002; Lin, 2002). Additional gene activities affecting stem cells are being identified but are yet to be recognized as part of a signaling pathway. *Nucleolar protein at 60B* (*Nop60B*), for example, encodes a pseudouridine synthase and is required intrinsically for germline stem cell survival. Specific alleles of the gene cause severe loss of germ cells, including stem cells and testicular atrophy (Kauffman *et al.*, 2003).

1.4.3.2. The Interaction between Germ Cells and Cyst Cells

After the stem cell divisions, the two cyst cells surround the presumptive gonialblast, thus forming a cyst (**Figure 3**). This process requires a complex interaction by different signaling cascades. The first step is the encapsulation of the gonialblast by the somatic cyst cells, which is dependent on epidermal growth factor receptor (EGFR) signaling (**Figure 4**). The EGFR pathway components Stem cell tumor (Stet) and Star (S), required for ligand activation in the cyst cells, are expressed in the gonialblast, indicating that the germ cell is the source of the signal (Schulz *et al.*, 2002). The EGF receptor and the downstream acting proteins monomeric GTPase Ras, the serine threonine kinase Raf, and the mitogen activated protein kinase Mek are expressed in the cyst cells, where they help to specify the cyst cell fate. Later on, EGFR activity in the cyst cells is necessary to promote the differentiation of the germline cell(s) and to control the number of mitotic divisions (**Figure 4**). Without the activity of the EGFR pathway, the stem cells divide symmetrically and both daughters retain stem cell identity (Kiger *et al.*, 2000; Tran *et al.*, 2000).

In a screen for mutants, a second signaling pathway was identified in the cyst cells, which prevents germ cells from overproliferation. The *punt* (*put*) and *schnurri* (*shn*) genes were shown to delimit this transient amplification of the germ cells (Matunis *et al.*, 1997). Both genes act within the somatic cyst cells, regulating a signal from the cyst cells to the germ cells (**Figure 4**). They are known components of the Decapentaplegic (Dpp)/transforming growth factor-β (TGF-β)-signaling pathway, where punt is one possible receptor for the ligand Dpp, and schnurri is the transcription factor acting downstream of the pathway. In testes, Dpp is apparently not involved, but there are two other TGF- β homologs, screw (scw) and 60A, one of which might be the ligand for punt in this system (Matunis *et al.*, 1997). This, however, needs to be tested experimentally.

The genes *bam* and the helicase *bgcn* code for germ cell intrinsic components of this pathway, and it is suggested that Bam and Bgcn are the targets of the signal from the cyst cells. Mutations in *bam* and *bgcn* lead to an accumulation of undifferentiated germ cells in both sexes, male and female (Gateff, 1982; McKearin and Spradling, 1990). Many details are known about their activity in the female system during oogenesis (see **Chapter 1.2**). However, in spermatogenesis, Bam and Bgcn seem to have different functions: in mutant females, the undifferentiated cells behave like stem cells, whereas in mutant males they exhibit characteristics of spermatogonial cells, too. In addition, overexpression of *bam* in females causes loss of stem cells (review: Deng and Lin, 2001; see **Chapter 1.2**), whereas in males there is no effect on the stem cells. Here, Bam and Bgcn participate in the assignment of spermatogonial cell fate, but the main signals are extrinsic (see above).

Recently, it was found that an additional signal between cyst cells and germ cells is transmitted via the TGF-β signaling pathway. The bone morphogenic protein (BMP5/8) ortholog glass bottom boat (Gbb), which represents a ligand for the TGF-β signaling pathway is expressed in the cyst cells. It provides a short-range signal to the GSC or the spermatogonia that are enclosed by these cyst cells, which suppresses Bam activity and, thus, maintains the spermatogonia

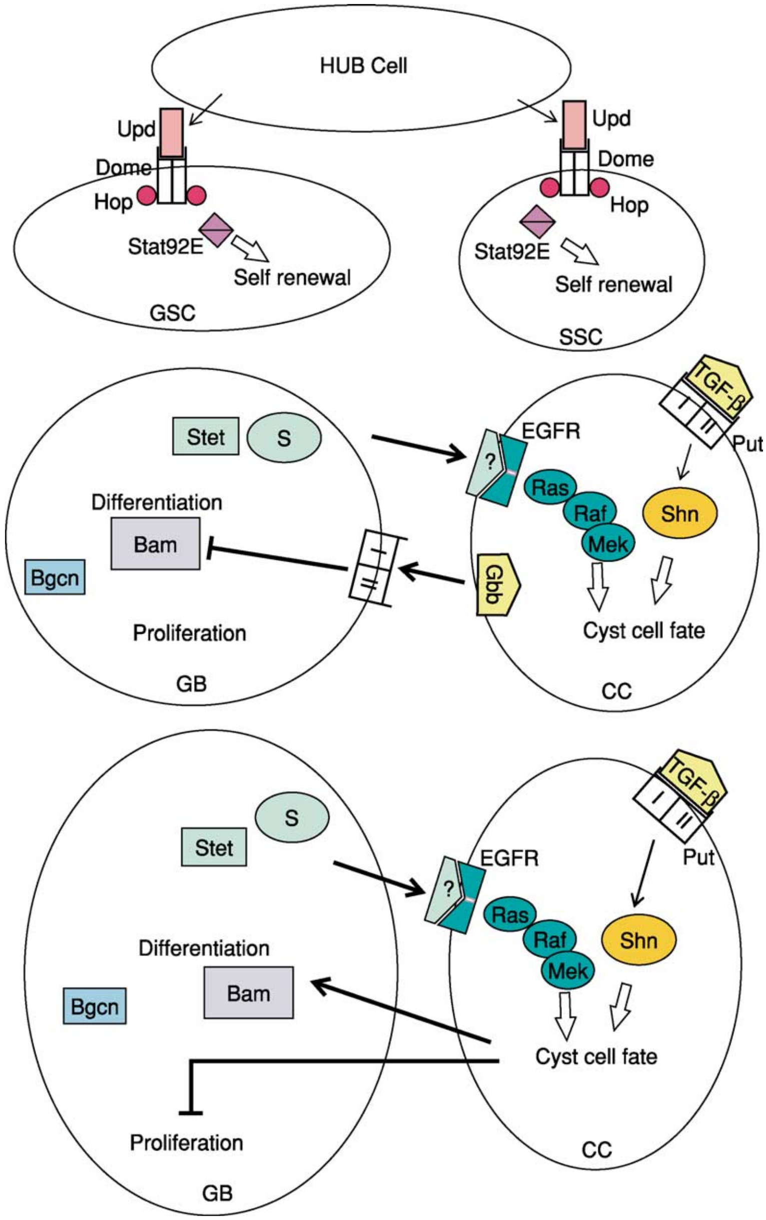

Figure 4 Signaling pathways and interactions between somatic and germ cells in the stem cell niche. The model summarizes the known interactions between somatic and germ cells in the stem cell niche. Only proteins that are genetically or experimentally shown to be expressed or involved in the testis are shown (see text for details). Bam, bag of marbles; Bgcn, benign gonial cell neoplasm; CC, cyst cell; Dome, Domeless; EGFR, epidermal growth factor receptor; GB, gonial blast; Gbb, Glass bottom boat; GSC, germline stem cell; Hop, Hopscotch; Stet, stem cell tumor; Mek, Mitogen activated protein kinase; Shn, Schnurri; SSC, somatic stem cell; Stat, signal transducer and activator of transcription protein; TGF-β, transforming growth factor β; Upd, Unpaired; I and II, type I and type II receptor of TGF-β.

in a proliferative state. With ongoing divisions, TGF-β signaling is proposed to decrease, resulting in an increased Bam activity, which leads to the block of proliferation and induction of differentiation of the enclosed germ cells (Shivdasani and Ingham, 2003).

In addition to signaling pathways, gap junctions may provide another important means of communication between germ and cyst cells. The germline specific innexin 4 zero population growth (Zpg) has been described, which is necessary for the survival of differentiating early germ cells in both sexes (Tazuke *et al*., 2002) and is found on the surface of spermatogonia primarily contacting the surrounding cyst cells.

In summary, at least two different signaling pathways are necessary to specify the somatic cyst

cell and to ensure the so far unknown signal for germ cell differentiation and proliferation control. It should be mentioned that after meiosis the cyst cells adopt two distinct functional fates and become oriented in a specific manner. The head cyst cell surrounds the region of the sperm heads and later becomes engulfed in the terminal epithelium, which seems to initiate the coiling and individualization process. The tail cyst cell encloses the entire tail region of the sperm bundle (Tokuyasu *et al*., 1972). A future research goal will be the identification of the signal cascade(s) needed to assign these different cell fates to the two cyst cells as well as the identification of additional germ cell intrinsic factors.

1.4.4. Regulation of Gene Activity

The enormous reorganization of cell shape during sperm morphogenesis requires a strictly regulated supply of proteins both with respect to time and space (see **Figure 3** for a summary of the regulatory processes). As the vast majority of transcription ceases after meiosis (Oliveri and Oliveri, 1965), transcripts required for spermiogenesis have to be synthesized during the extended primary spermatocyte phase. This requires stability of the mRNAs over several days. Furthermore, many mRNAs are translationally repressed until the encoded proteins are required for a distinct step of sperm morphogenesis (see below for molecular details). At the transcriptional level, mRNAs are differentially regulated by distinct transcription initiation complexes depending on their time of translation (see below).

1.4.4.1. Very Short Regulatory Regions for Transcriptional Control

Transcriptional regulation can be studied *in vivo* through the employment of reporter gene assays (**Figure 1e** and **f**) and the P-element transformation system. This approach has revealed that, in general, the control regions of genes which are expressed specifically in the testis, are extremely short. Genes expressed in the soma and the germline often contain a short testis-specific promoter, as exemplified by the male-specific promoter of the *dihydroorotate dehydrogenase* (*dhod*) gene (Yang *et al*., 1995). Genes, that are expressed in the male and female germline often contain sex-specific promoters, as exemplified by *gonadal* (*gdl*) (Schulz *et al*., 1990). For simplicity, we first discuss here the transcription properties of the *β tubulin* genes, *βTub56D* (*β1 tubulin* gene) and *βTub85D* (*β2 tubulin* gene). These are expressed in germ cells, while the somatic cyst cells express β1 tubulin and β3 tubulin (Kaltschmidt *et al*., 1991). The β1-tubulin isotype is also expressed in stem cells and spermatogonia, while the male germline-specific β2-tubulin isotype is the only β2-tubulin isotype expressed from the meiotic prophase onwards (Hoyle and Raff, 1990; Kaltschmidt *et al*., 1991).

In the early, mitotically active stem cell and spermatogonial stages, *β1 tubulin* gene transcription is dependent on cap site upstream gene sequences located between −45 and −191, while expression in the somatic cyst cells is guided by elements in the large intron of the gene (Buttgereit and Renkawitz-Pohl, 1993). In spermatocytes, the *β1 tubulin* gene is silenced and the *β2 tubulin* gene (*βTub85D*) is activated instead (see **Figure 1e** and **f** for reporter gene assay). Loss-of-function mutants of the *β2 tubulin* gene show that this β2-tubulin isotype is essential for the formation of the meiotic spindle and the axoneme (Kemphues *et al*., 1982). The β2-tubulin mRNA is translated immediately after transcription and is very stable.

Michiels *et al*. (1989) showed that very short upstream regions (53 bp) and the 5′untranslated region of the β2-tubulin gene are sufficient to drive tissue specific and temporally regulated expression, a feature characteristic of genes that are transcribed during the spermatocyte phase. A 14 bp regulatory element β2UE1 (region −51 to −38), which is conserved in function between the distantly related species *D. melanogaster* and *D. hydei*, is indispensable for tissue specific and temporal expression, while a second element, β2UE2 (region −32 to −26), close to the transcription initiation site is responsible for high level of expression. Alternatively, however, the β2UE1-element was found to be unable to drive spermatocyte-specific expression of a reporter gene efficiently upon linkage to the hsp70 promoter or the β3-tubulin promoter, suggesting that different transcription initiation mechanisms are used in spermatocytes (Michiels *et al*., 1991).

Another 18 bp element in the 5′ UTR of the β2-tubulin mRNA, β2DE1 (+48 to +65), forms a predicted stem and loop structure and is required for mRNA stability (Michiels *et al*., 1993). It is very likely that this β2DE1 element has dual function as it regulates promoter strength in addition to mRNA stability in combination with an initiator (Inr) element. The Inr, a 6–8 bp sequence encompassing the transcription initiation site, is thought to function either as a TATA box analog in TATA-less core promoters or as an enhancer of TATA box function in TATA box containing promoters (Santel *et al*., 2000 and literature cited therein).

The *Drosophila Mst(3)CGP* gene family members encode the putative satellite protein components

mentioned above (Section 1.4.2.4.1). These proteins contain large clusters of cysteine–glycine–proline repeats (Kuhn *et al*., 1991). Their genes are also characterized by short upstream transcriptional control regions (Kuhn *et al*., 1988; Gigliotti *et al*., 1997). In this case, the 5′ UTR contains a 12-nucleotide long translational control element (TCE) with regulatory potential both at the RNA and the DNA level (Kempe *et al*., 1993). It mediates negative translational control (see Section 1.4.4.3) and is also capable of mediating correct transcriptional activation *in vivo* of a silent β2-tubulin gene fragment, which lacks the β2UE1 promoter element. Protein binding occurs at the TCE both at the RNA and the DNA level (Kempe *et al*., 1993). Finally, as is the case with the *Mst(3)CGP* gene family, expression of *don juan* is controlled by short upstream regions (23 bp together with the 5′ UTR are sufficient) in combination with downstream sequences, located between +54 and +115 (Blümer *et al*., 2002). This part of the UTR also harbors the translational repression element (TRE) of the *don juan* mRNA (see Section 1.4.4.3).

In summary, all testis-specific promoters achieve high tissue-specific expression by a combination of short upstream sequences mediating tissue specificity and downstream elements necessary for achieving high transcript levels and mRNA stability or translational repression. Messenger RNAs that are translated before and after meiosis are differentially regulated by distinct transcriptional initiation complexes.

1.4.4.2. Distinction between mRNAs that will be Translated Directly and those that will be Translationally Repressed

White-Cooper *et al*. (1998) analyzed the presence of mRNAs that are subject to premeiotic translational repression in a collection of meiotic arrest mutants (block of the transition from G2 to meiosis I) of the genes *aly*, *can*, *mia*, and *sa*. In contrast to the wild-type situation, the translationally controlled mRNAs of the *don juan*, *Mst87F*, *Mst84Da-d*, *Mst98Ca/b*, and *janus B* genes are not transcribed in these mutants. This suggests that genes encoding translationally repressed mRNAs are under differential transcriptional control that is dependent on Aly, Can, Mia, and Sa (review: Fuller, 1998). This hypothesis is strongly supported by the fact that *can* encodes a spermatocyte-specific $TAF_{II}80$ (Hiller *et al*., 2001). TAFs are components of the general transcription factor complex TFIID, which interacts with RNA polymerase II and additional transcription factors. This interaction is essential to initiate transcription. Thus, in *can* mutants, the target genes mentioned above cannot be transcribed. This regulatory mechanism allows the spermatocyte to distinguish at the transcriptional level, through the use of distinct transcription initiation complexes, between the mRNAs that will be immediately transferred to the ribosomes for translation and those that will be translationally repressed for several days until the terminal differentiation program of spermiogenesis is initiated.

Besides the regulation exerted by Can at the individual gene level for transcription initiation, it has been suggested by White-Cooper *et al*. (2000) that modulation of chromatin conformation may also play a major role in selection during spermiogenesis. They proposed that *aly* may play a role at the chromatin level by repressing certain genes and allowing the activation of others, which are essential for meiosis and spermiogenesis. This notion is supported by the chromatin localization of Aly during the spermatocyte stage. As there is no evidence for direct binding of Aly to DNA, it is likely that this protein plays a role in chromatin structure modulation, perhaps in response to intrinsic or extrinsic signals, as suggested by its translocation from the cytoplasm to the nucleus during the early spermatocyte stage. Thus, it is envisaged that Aly reorganizes the chromatin so that the genes for the meiotic cell cycle and the sperm differentiation program become accessible to specific transcription complexes including male germline-specific TAFs like cannonball.

Recently, *comr* mutants were characterized, and were found to cause defects indistinguishable from those of the *aly* mutants. As is the case with the latter, a large number of genes like *Mst87F* (mRNAs under translational repression) are not transcribed in the *comr* mutants. The Comr protein is also nuclear, and it has been proposed that it regulates transcription at the chromatin level in concert with Aly. Both proteins are degraded when germ cells enter the meiotic divisions concomitant with the general turn-off of transcription (Jiang and White-Cooper, 2003).

In addition, a homeodomain containing transcription factor TGIF (TG-interacting factor), encoded by the nearly identical and tandemly arranged genes *achintya* (*achi*) and *vismay* (*vis*), is essential for male fertility and for the activation of the developmentally regulated program of transcription in spermatogenesis (Ayyar *et al*., 2003; Wang and Mann, 2003). Again, spermiogenesis-relevant genes like *don juan*, *fuzzy onion*, *gonadal*, *janus B*, and *Mst87F* are not transcribed in mutants lacking TGIF. Null mutants exhibit the same meiotic arrest phenotype as the *aly* mutation (Ayyar *et al*., 2003), and the protein coimmunoprecipitates with Aly and Comr

suggesting that complex formation is required for proper regulation (Wang and Mann, 2003).

1.4.4.3. Translational Repression of mRNAs and Differential Release from Repression

Since transcriptional activity ceases after the long meiotic prophase, the meiotic divisions and the entire process of sperm morphogenesis rely on presynthesized mRNAs. In particular, the complex morphological alterations necessary for the formation of fully differentiated sperm require a large number of proteins to be synthesized in a correct temporal and spatial manner in order for proper development of sperm to occur. Therefore, a large number of mRNAs must be stored and translationally silenced after synthesis during the spermatocyte stage, and selectively translationally activated at specific time points during spermiogenesis. This implies that translational repression should be a very general phenomenon during spermatogenesis, and allows the assumption that common control elements (*cis* and *trans* acting) may be used for many mRNAs.

The first case studied was that of the *Mst(3)CGP* gene family, which encompasses seven members encoding structural proteins of the sperm tail (see Sections 1.4.2.4.1 and 1.4.4.1). They are all transcribed during the spermatocyte stage but translational activity is only observed during late spermiogenesis, when spermatids have elongated fully (Kuhn *et al*., 1988; Schäfer *et al*., 1993; Gigliotti *et al*., 1997). Concomitant with translational activation, secondary polyadenylation of the mRNAs in the cytoplasm has been observed leading to a longer and heterogeneous transcript size (Schäfer *et al*., 1990, 1993; Kuhn *et al*., 1991). This phenomenon of secondary (or cytoplasmic) polyadenylation has been observed in a number of cases with translational control (Richter, 1999). Surprisingly, however, in mammalian spermatogenesis, where translational control phenomena have also been described, translationally controlled transcripts diminish in size due to shortening of the poly(A) tail when they are translationally activated (Braun, 1990).

Sequence comparisons revealed a conserved 12-nucleotide long element termed TCE in the 5′ UTR of all these mRNAs, which is invariably located at nucleotides +28 to +39 relative to the transcription cap site. Sequence modifications as well as mislocalization of this TCE lead to loss of translational repression. Thus, premature translation is observed in the spermatocyte stage, and cytoplasmic polyadenylation does not occur (Schäfer *et al*., 1990; Kempe *et al*., 1993). However, when the TCE is correctly placed in the *β2-tubulin* gene, it does not confer translational control to the mRNA encoded by this gene (Kempe *et al*., 1993). Instead, it is transcriptionally activated but translated concomittant with transcription. This supports the statement made earlier that translational control can only occur if the RNA has been transcriptionally activated from an appropriate promoter (see Section 1.4.4.2).

Even though all seven members of the *Mst(3)CGP* gene family contain the same TCE, negative translational control apparently is achieved in different ways. In a study that compared the expression of the divergently transcribed genes of the *Mst84D* cluster, *Mst84Da* and *Mst84Db*, it was found that *Mst84Da* is translationally regulated by a short segment containing the TCE as is the case with *Mst87F*. In the case of *Mst84Db*, however, a short segment within the open reading frame, which is totally unrelated to the TCE, mediates translational repression. Furthermore, translational activation is only achieved when the 3′ UTR sequences are present as well. This gene region confers mRNA stability, which is a prerequisite for translational activation late in spermiogenesis (Gigliotti *et al*., 1997). Thus, while the function of the TCE in this case remains to be elucidated, this gene offers the chance to uncouple the phenomenon of translational repression from that of translational activation. Alternatively, translational activation in this case could be a default mechanism after the RNA has persisted until this late developmental stage.

TCE-like sequences could be detected within the 5′ UTR of several other genes. The *janusB* gene (Yanicostas and Lepesant, 1990) contains a TCE close to the translation initiation codon that is necessary for translational control of the mRNA. Similarly, the gene *Mst59D* contains a bipartite TCE sequence, which also proved necessary for translational repression (Huang *et al*., in preparation).

Since it has been hypothesized that many, if not all, genes that are subject to translational control in spermatogenesis may contain a TCE (Schäfer *et al*., 1995), we searched for this element in the *don juan* gene mRNA, which has also been shown to be translationally controlled (see Section 1.4.2.4.3, Santel *et al*., 1997). Even though the 5′ UTR contains such a TCE sequence, at a different position compared to the *Mst(3)CGP* gene family, the relevant sequence does not mediate translational control in this case. Instead, a neighboring region that is capable of forming a secondary structure confers translational repression to the *don juan* mRNA.

Because it is functionally distinct from the TCE sequence, it has been termed TRE (translational repression element; Blümer *et al.*, 2002).

Individual translational activation of the different mRNAs is an essential prerequisite for correct sperm development. Analyses in various mutant strains indeed have shown that the time point of translational activation for the Mst98C mRNAs is preceded by that of the *don juan* mRNA (Blümer *et al.*, 2002). So far, nothing is known about this aspect of translational regulation in *Drosophila* spermatogenesis.

Because translational control is mandatory for proper sperm development, RNA binding proteins have been implicated in male fertility (Venables and Eperon, 1999). Several genes encoding relevant to RNA binding proteins have been described, some operating in both sexes (Lantz *et al.*, 1992; Webster *et al.*, 1997) and others being specific for the male germline (Karsch-Mizrachi and Haynes, 1993; Heatwole and Haynes, 1996; Haynes *et al.*, 1997) but, with the exception of *boule*, a homolog of the mammalian *Deleted in Azoospermia* (*DAZ*) gene (Eberhart *et al.*, 1996), their targets have yet to be determined.

The *boule* gene has been found to encode an RNA binding protein (Eberhart *et al.*, 1996). Mutations in this gene cause a meiotic entry defect. It was shown that this is due to lack of Twe synthesis, a meiotic Cdc25 protein, since expression of Twine from a chimeric *β2 tubulin* gene construct, in which the Twine coding sequence substituted for that of *β tubulin*, could rescue this mutation. Therefore, *boule* must encode a translational activator necessary for Twine translation (Maines and Wasserman, 1999).

In accordance with such a function, Boule has been shown to localize to a specific region of the nucleus and to translocate to the cytoplasm at the onset of meiosis (Cheng *et al.*, 1998). The authors speculate that Boule may have additional RNA targets that encode proteins for sperm morphogenesis, and that Boule may, therefore, coordinate the process of meiosis and spermatid differentiation (Maines and Wasserman, 1999). This raises the possibility that Boule may also be involved in the derepression phenomena discussed above. This can be further analyzed once the RNA sequences to which Boule binds are identified. The central importance of translational control during spermatogenesis is underlined by the fact that *boule* has been found to be highly conserved not only in sequence but also in function. Indeed, the newly identified human *boule* gene, an additional member of the *DAZ* gene family, can rescue a *boule* mutant fly to the same extent as a fly *boule* transgene (Xu *et al.*, 2003).

1.4.5. Insights from Other Insect Species

1.4.5.1. Control of Spermatogenesis

Besides *D. melanogaster*, spermatogenesis in insects has been best analyzed in *D. hydei*, particularly the Y chromosome fertility factors (review: Hackstein and Hochstenbach, 1995). Instead of the four mitotic divisions that occur in *D. melanogaster*, the spermatogonia in *D. hydei* go through only three mitotic divisions before entering meiotic prophase I, a typical example of the species-specific number of mitotic amplification steps. The sperm are unusually long, i.e., 10 mm in length (**Figure 2**). The axoneme as well as the meiotic spindle contain the testis specific β2-tubulin isotype and even the tissue-specific regulation of this gene is conserved between the two species (Michiels *et al.*, 1989).

The number of genes needed for correct sperm development is still unclear. In microarray analyses, 14% of the genome (2063 genes) were found to be testis-biased in their expression compared to only 8.5% (1226 genes) that have ovary-biased expression, and another 3% of the genes that are expressed in both germlines (M. Parisi and B. Oliver, submitted). In contrast to genes that have female-biased expression, genes that exhibit selective or preferential expression in the male germline are underrepresented on the X chromosome of *Drosophila*. Using comparative genomics, X chromosome linked genes were shown to be exceptionally poorly conserved in the mosquito *Anopheles gambiae*, suggesting that the X chromosome, in general, is not a favored location for genes expressed selectively in males (Parisi *et al.*, 2003). The reason could be either that in males, which only have one X chromosome, a mutation would immediately become effective, or that the X chromosome is inactivated early during spermatogenesis preventing effective transcription.

1.4.5.2. Sperm Maturation and Function

In several species of the *D. obscura* group, sperm of different lengths have been observed. In *D. subobscura*, for example, motile sperm show a clear length dimorphism but have similar morphology (Pasini *et al.*, 1996). It was shown that females preferentially store long sperm in their spermathecae and seminal receptacle (Bressac and Hauschteck-Jungen, 1996; see **Chapter 3.9**). Furthermore, only long sperm were present within *Drosophila* eggs upon fertilization of six different species, indicating that only the long class of sperm is fertilization-competent (Snook and Karr, 1998; see **Chapter 1.6**). In addition, it has been found that sperm size can vary significantly among closely related species of insects,

suggesting a rapid evolution of this sexual trait (Swallow and Wilkinson 2002; Hosken, 2003). It has been suggested that this occurs as a sperm-female coevolution, in which sperm size is a correlated response to a changing female reproductive tract size (Miller and Pitnick, 2002).

In the Lepidoptera, dimorphic sperm have also been analyzed (Friedländer, 1997). Only eusperm are capable of fertilization, while parasperm are not, as their DNA is fragmented and degraded. It has been proposed that parasperm have auxilliary functions for the eusperm, such as a nutritive role, facilitation of maturation, and help with the transport from the testes to the female reproductive tract and sperm storage organs. Nonfertile parasperm, which in the case of the tobacco hornworm, *Manduca sexta*, can account for as much as 96% of the ejaculate, may also act as a factor that delays the remating of females, thus reducing the potential for sperm competition (Cook and Wedell, 1999; see also Hodgson, 1998).

Sperm maturation has been found to be under circadian clock control, which is established several days after pupation (Giebultowicz and Joy, 1992; see **Chapters 3.12** and **4.11**). In moths, sperm bundles are released in a two-step circadian rhythm. Release of sperm to the *vas deferens* occurs during a few hours in the evening, and transfer to the seminal vesicles occurs for a few hours in the morning. The *period* (*per*) gene expression has been demonstrated to occur in the region of the terminal epithelium of the moth *vas deferens*, a region that is important for sperm maturation and release (Giebultowicz *et al*., 1997). In *Drosophila*, *per* expression was also detected in the terminal epithelium suggesting the existence of a circadian rhythm for sperm release in flies also (review: Giebultowicz, 2000).

1.4.6. Conclusions and Perspectives

Most of the progress in understanding insect spermatogenesis in recent years has come from the identification of regulatory networks within the germ cells, on the one hand, and the analysis of cell–cell interactions, on the other. For both of these aspects, however, many questions remain unanswered.

With respect to cell interactions, the role of the hub cells and additional signals required for the maintenance of the stem cell fate remain to be elucidated. In particular, the role played by other cell contact regions like gap junctions has yet to be studied in detail. In addition, as mentioned earlier, the very distinct interaction between the germ cells and the two different types of cyst cells, the head and tail cyst cells, has not been studied at all thus far. Among others, it remains to be shown how this specific interaction is regulated and what is the significance of the alignment. After meiosis, the mechanisms underlying the degradation of histones and the switch to a protamine based chromatin structure remain to be elucidated.

From more recent studies, the conclusion is emerging that control points exist at various stages of spermatogenesis. Like in many other developmental processes, the entry into meiosis and initiation of the differentiation program are coordinated and controlled by a number of genes. It is evident that all the players have not been revealed yet. The identification of some of the control genes, however, will undoubtedly facilitate the identification of others and should permit the unravelling of the entire network. The immense difference in detailed knowledge of the molecular processes that are involved in the control of oogenesis and spermatogenesis has diminished in recent years. As it turns out that more genes are preferentially or specifically expressed in the male gonad than in the female one indicating that the regulatory network and the detailed cell–cell communications during the development of the male germ cell line process may exceed the complexity found in the female one.

Recently, the scientific interest in understanding the regulation of insect spermatogenesis has increased greatly for two very different reasons. First, *Drosophila* turns out to be a suitable model for studying human infertility problems. Second, manipulation of male fertility is a potential way of preventing the growth of insect pest populations, which represent a threat for mankind either by spreading diseases or by causing immense destruction of agricultural crops. The large amount of molecular information gathered in recent years should speed up progress in both these areas.

Acknowledgments

We thank Dr Ulrich Schäfer for critical reading of the manuscript, and Heike Sauer and Anke Eberhardt for excellent secretarial assistance. We also thank Richard Bekemeier for providing Figure 2. 1.5 Gonadal Glands and Their Gene Products

M F Wolfner, Cornell University, Ithaca, NY, USA
Y Heifetz and S W Applebaum, The Hebrew University of Jerusalem Rehovot, Israel

1.5.1. Introduction

The reproductive tracts of male and female animals contain a variety of glands and tissues whose products aid in reproduction. These gonadal glands and their products are crucial in various aspects of insect reproduction. Male reproductive glands provide proteins, peptides, and other molecules that are transferred to females during mating and contribute directly to female reproductive events. Female reproductive glands produce substances that are thought to support the gametes in their storage and meeting, to protect eggs, and, possibly, to interact with male-derived products.

Here, studies of discrete glands or glandular tissues associated with the reproductive system of insects are reviewed. Gonadal glands vary from primitive secretory epithelial cells along the wall of the reproductive tract to complicated glandular structures (reviews: Adiyodi and Adiyodi, 1975; Gillott, 1988). In this chapter, the term "male gonadal glands" is used to refer to male accessory glands (sometimes called paragonia) and also the secretory epithelia of the ejaculatory duct, ejaculatory bulb, and testis sheath (Figure 1). For females, the term "gonadal glands" includes the female accessory glands (sometimes called parovaria) and glandular structures or tissue associated with the spermatheca (otherwise called spermathecal glands) (Figure 1). Various modifications of glands, glandular tissues, or glandular functions occur in different insect orders, and species-specific functions have evolved. The original names of the organs/tissues and/or functions have been used, when expedient.

Early studies established the composition and role of gonadal gland gene products and their putative functions. Others provided ecological considerations of presumptive roles of gonadal gland products,

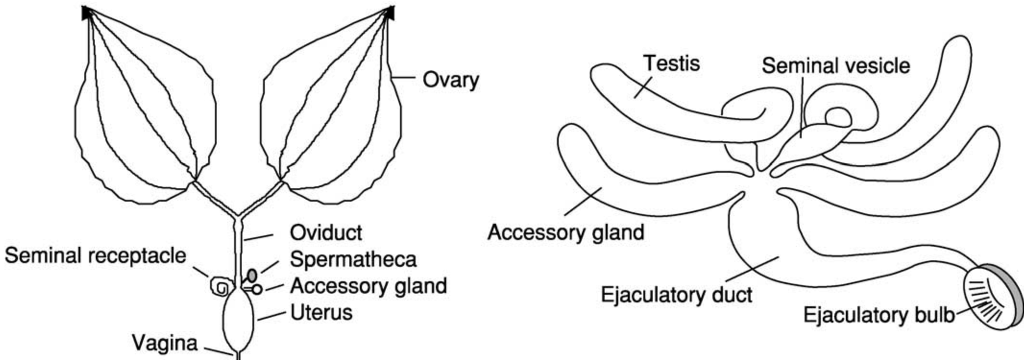

Figure 1 Reproductive tract of *Drosophila melanogaster*, showing the locations of gonadal glands including in females (left panel) the female accessory glands and spermathecae and in males (right panel) the male accessory glands, ejaculatory duct and ejaculatory bulb. Biol. 27*, 179–192; © Elsevier.)

either produced in such tissues or sequestered therein. More recently, studies have focused on identifying the factors made in the gonadal glands, and their actions in reproduction. In this chapter, the gonadal glands are discussed, and then, selected examples of male-derived products that are transferred to the female during mating and mediate male–female interactions in reproduction are presented, as well as examples of female-derived products known or likely to be involved in subsequent reproductive events. This material will also assist in viewing current studies on the molecular biology and genetics of gonadal gland products in a broader perspective.

1.5.1.1. Historical Perspectives

1.5.1.1.1. The discovery of important roles of gonadal gland secretions Insect females exhibit a variety of changes after mating. Depending on the species, they either initiate or increase their production of eggs after mating (for examples of reviews and references for *Drosophila melanogaster*, see Boulétreau-Merle, 1974; Wolfner, 1997; Chapman, 2001; Wolfner, 2002; Kubli, 2003; also **Chapters 1.3** and **3.9** and below). Mated insect females also store sperm, as do all animals that carry out internal fertilization (e.g., reviews: Neubaum and Wolfner, 1999b; Bloch Qazi *et al.*, 2003). Female insects often undergo changes in post-mating behavior, such that they no longer attract, or actively reject, subsequent courting males (for examples of reviews and references for *D. melanogaster*, see above and Manning, 1962, 1967; Swanson, 2003; and below). Factors transferred from males' gonadal glands during copulation often induce these changes. Such substances have been reported in Diptera, Orthoptera, Lepidoptera, and Coleoptera (reviews: Gillott, 1988, 2003). For example, in reproductively-mature female moths, biosynthesis and release of sex-pheromones indicate a female's receptivity to mating, and attracts conspecific males (see **Chapter 3.14**). Mated females arrest sex-pheromone production and cease attracting males. This has been demonstrated in many moth species, e.g., *Bombyx mori* (Ando *et al.*, 1996); *Choristoneura fumiferana* and *C. rosaceana* (Delisle *et al.*, 2000); *Epiphyas postvittana* (Foster, 1993); *Lymantria dispar* (Giebultowicz *et al.*, 1991); *Argyrotaenia velutinana* (Jurenka *et al.*, 1993; Kingan *et al.*, 1993); *Plodia interpunctella* (Rafaeli and Gileadi, 2000); *Helicoverpa zea* (Raina, 1989); and *Heliothis virescens* (Ramaswamy *et al.*, 1996). Cessation is permanent or transient, correlated with whether a species exhibits single or multiple mating. In addition to terminating sex pheromone production, mated female moths cease "calling" behavior – specific postures and wing fanning – and start ovipositing. Changes in post-mating willingness to re-mate are also seen in Diptera, including *D. melanogaster* and *Aedes aegypti*, and here too have been shown to be triggered by substances transferred from male gonadal glands (Fuchs and Hiss, 1970; Chen *et al.*, 1988), as will be discussed later.

Tissue transplantation, and the injection of extracts from gonadal glands, first provided an indication that the substances that trigger, and in some cases further regulate, these changes derive from glands of the male reproductive tract, and are donated to the female during mating. The male origin of these regulators was shown by the fact that virgin females did not mate after male reproductive tissues were transplanted into their body cavity. Such females showed physiological and behavioral

characteristics normally associated with mated females. For example, extracts of male *Helicoverpa armigera* reproductive accessory glands inhibited pheromone biosynthesis when injected into unmated females (Fan *et al*., 1999b), and transplantation of male accessory glands into unmated *D. melanogaster* caused the females to increase egg production/laying and to reject the advances of courting males (Garcia-Bellido, 1964; Merle, 1968). These results suggested strongly that molecules from the male must act through the female's hemolymph to affect her behavior and physiology. In another example, the deposition of fully developed and mature oocytes of many locusts and grasshoppers is stimulated by mating and can also be induced by implantation of male accessory glands, or injection of their extracts, into females (*Melanoplus sanguinipes* (Pickford *et al*., 1969); *Schistocerca gregaria* (Leahy, 1973)).

Further evidence that the products of male gonadal glands were important in females' post-mating responses came from studies in which the male tissues were depleted of, or made deficient in, those secretions. Most of these studies were carried out in *D. melanogaster*, in order to take advantage of its genetic techniques. *Drosophila* males that have mated multiple times still transfer sperm, but they have deflated accessory glands, suggesting that the tissue has been depleted of contents (Hihara, 1981). Mates of these males did not show the normal elevation of egg deposition or depression of receptivity to remating. This suggested that some component of the male reproductive tract other than sperm, possibly from the male's accessory glands, was responsible for the changes in mated females. Transgenic males deficient in accessory gland function were created by expression of a transgene encoding an intracellular toxin (Kalb *et al*., 1993), or by expression of particular forms of the *paired* (*prd*) gene, that allowed viability but prevented accessory gland development (Xue and Noll, 2000). Mates of these males did not show the behavioral or physiological changes associated with mating, and had deficient sperm storage. They also utilized the sperm they had stored inefficiently, such that they produced a few progeny unless accessory gland products were supplied by a subsequent mating. Experiments with males singly mutant in some accessory gland or ejaculatory duct products (see below) confirmed the roles of products of these tissues in post-mating responses (Gilbert *et al*., 1981; Cavener and MacIntyre, 1983; Whalen and Wilson, 1986; Ludwig *et al*., 1991; Herndon and Wolfner, 1995; Neubaum and Wolfner, 1999a; Heifetz *et al*., 2000; Saudan *et al*., 2002; Liu and Kubli, 2003).

The presumptive function of male accessory gland secretions was also evaluated by surgical manipulation of female responsive tissues. Protracted post-mating nonreceptivity is imposed in female grasshoppers (*Gomphocerus rufus*) by a component of the "white secretory tubule 1" of the male's accessory gland. This male-derived component is assumed to stimulate chemoreceptors located at the entry of the spermathecal duct into the endbulb (Hartmann and Loher, 1999). Ablation of the presumptive chemoreceptors, or surgical intervention in the neural pathway to the central nervous system (CNS), prevented the induction of nonreceptivity. Although this suggests the involvement of a direct neural pathway, caution must be exercised to rule out the possibility that behavioral responses after such surgical procedures were not due to stimulation of mechanoreceptors.

Although their study has been less extensive than that of male gonadal substances, female gonadal gland substances have also been shown to be important in reproductive physiology. For example, removal of *Musca domestica* female accessory glands (colleterial glands) reduced fertility by over 99% (Leopold and Degrugil, 1973). In another example, a volatile compound (pentanoic acid) produced by the female accessory glands (Comstock-Kellog glands) of the desert locust *S. gregaria* (Slifer, 1940, cited in Uvarov, 1966) is active in the stimulation of premating behavior of conspecific males (Njagi and Torto, 2002).

1.5.1.1.2. Identification of gonadal gland substances Two general methods have been used to identify gonadal gland products.

In several cases, extracts of gonadal glands have been fractionated chemically, and functions have been assigned on the basis of bioassays. Perhaps the best known molecule found in this manner is the "sex peptide" (also called SP; Acp70A) of *D. melanogaster*, which was identified by assaying fractions of male accessory gland methanolic extracts for their ability to stimulate egg deposition or decrease receptivity when injected into the hemolymph of unmated females (Chen *et al*., 1988). Fractionated extracts from mosquito accessory glands have also yielded peptides that affect behaviors (Lee and Klowden, 1999). In some cases, gel electrophoresis or biochemical assays of gonadal gland products provided functional information. For example, electrophoretic analysis of proteins from gonadal glands and from spermatophores of the beetle *Tenebrio molitor* indicated that spermatophore proteins were made in male accessory glands (Happ *et al*., 1977; Black *et al*., 1982; Grimnes *et al*., 1986). Similar analyses showed that a major component of the mating plug in

D. melanogaster derives from the ejaculatory bulb (Ludwig *et al*., 1991), and that a lysine-rich 12 kDa protein transferred with the spermatophore to female *Locusta migratoria* came from the opalescent gland of the male accessory gland (Lange and Loughton, 1985). Biochemical analysis of gonadal gland extracts led to the identification of protease inhibitors in the male accessory gland of *D. funebris* (Schmidt *et al*., 1989) and *S. gregaria* (Hamdaoui *et al*., 1997, 1998) (review: Simonet *et al*., 2002), lipases in male gonadal glands of sand flies *Phlebotomus papatasi* (Rosetto *et al*., 2003a) and *D. melanogaster* (Smith *et al*., 1994) and esterases and dehydrogenases in the *D. melanogaster* male's ejaculatory duct and some parts of the female reproductive tract (Gilbert *et al*., 1981; Cavener and MacIntyre, 1983; Feng *et al*., 1991). Finally, gel assays have identifed antimicrobial peptides in extracts of male or female gonadal glands of *D. melanogaster* and the medfly *Ceratitis capitata*, respectively (Marchini *et al*., 1991; Samakovlis *et al*., 1991; Lung *et al*., 2001a).

With the advent of gene technologies, hybridization or expressed sequence tag (EST) methods have been used to identify products of gonadal glands. In *D. melanogaster*, screens for differential gene expression have identified male-specific RNAs expressed in male accessory glands (Schäfer, 1986; DiBenedetto *et al*., 1987; Wolfner, 1997), eventually leading to a comprehensive EST screen for these "*Acp*" genes in *Drosophila* (Swanson *et al*., 2001). Genes identified by these screens can then be tested for function, either by *in vitro* or injection methods analogous to the ones described above or by expression or RNA interference (RNAi) (e.g., Chen *et al*., 1988; Aigaki *et al*., 1991; Chapman *et al*., 2003b; Brown *et al*., 2003) or, in *D. melanogaster*, by genetic techniques (e.g., Herndon and Wolfner, 1995; Neubaum and Wolfner, 1999a; Heifetz *et al*., 2000; Liu and Kubli, 2003). Finally, gonadal products of known function in one insect have been tested for functions in others, to determine whether sequence- and functionally-related molecules might exist in the other insect (Fan *et al*., 1999b, 2000; see Section 1.5.1.2).

1.5.1.2. Nomenclature

Structure-, function-, or family-based rules and conventions for nomenclature of lipids and enzymes, and genome-based conventions for naming genes are firmly established and usually unambiguous. However, the situation is more complex for bioactive peptides and proteins. For these, names are often assigned based on the first functions detected by *in vivo* assays. For example, among *D. melanogaster* paragonadal products, the peptide mentioned earlier, that is sex (male)-specific and affects egg production and mating-receptivity in mated females was named sex peptide (SP) (Chen *et al*., 1988), and a polypeptide that regulates ovulation, was called ovulin to reflect its function (Heifetz *et al*., 2000). As evocative and therefore useful as these common names are, their use can do a disservice, when additional important functions for the same molecule are discovered by subsequent assays. As a case in point, adipokinetic hormone (not a paragonadal product; simply used here to illustrate nomenclature issues) was named for its ability to mobilize lipids from the fat body (see **Chapter 4.6**), but this name masks its additional function in inhibiting protein synthesis (Carlisle and Loughton, 1979). Names are sometimes assigned based on tissue of origin, e.g., pEB-me: protein from the Ejaculatory Bulb of *D. melanogaster* (Ludwig *et al*., 1991; Lung *et al*., 2001b), or tissue of origin plus chromosomal position, e.g., Acp62F for *D. melanogaster* Accessory gland protein from chromosome position 62F (Wolfner *et al*., 1997), or Dup99B for *Ductus ejaculatorius* protein from chromosomal position 99B (Saudan *et al*., 2002).

Confusion can result when the same molecule has a double designation. For example, *D. melanogaster* SP (Chen *et al*., 1988) is also designated Acp70A (e.g., Wolfner, 2002) and *D. melanogaster* ovulin is also called Acp26Aa (Monsma and Wolfner, 1988; Monsma *et al*., 1990; Heifetz *et al*., 2000). Further confusion results when molecules identified in one species are assayed in another species and their cross-reactivity suggests that the recipient species may have a molecule structurally and/or functionally similar. For example, SP elicits post-mating reactions of the adult female African bollworm, *H. armigera*, analogous to those elicited in *D. melanogaster* (Fan *et al*., 1999b, 2000), suggesting that *H. armigera* makes a similar molecule that elicits these effects (see Section 1.5.1.2).

To unify the nomenclature, the authors propose that each gene be referred to with a single name. When all experiments are conducted on the species in which the gene was identified, species designation need not be indicated (apart from an initial statement of the species used in the paper) but when cross-genera or cross-species studies are carried out, an italicized three lettered species designation should precede the name of the gene or peptide. For example, in the study noted above, using the designation *Drm*-SP (= *Drm*-Acp70A) to identify the origin of the peptide that elicits post-mating responses in the moth *H. armigera* is suggested. Cross-reactivity of *Drm*-SP suggests that an ortholog

Hea-SP will eventually be found in the moth (Fan *et al*., 1999b). Designations based on specific function (e.g., SP), where known, are less cumbersome than ones based only on isolation method or genetic map position in a given organism (e.g., Acp70A), but may be confusing if functions differ in different organisms. Therefore it is proposed that functional names be used with caution and always with co-designation of their systematic or generic name, the first time they are mentioned in the text of a report. Since the functions of many gonadal gland products remain to be determined, their systematic names should be used exclusively until after functions are determined.

1.5.1.3. What are Gonadal Glands?

The gonadal glands of males (**Figure 1**) are the male accessory glands, the seminal vesicle (where sperm are stored prior to transfer to females), the ejaculatory duct (through which ejaculate passes on its way from the male to the female), and the ejaculatory bulb (a pump that also produces some components of the ejaculate). In females, the gonadal glands include the female accessory glands and the spermathecal glands. Often, these glands are simple single layers of secretory cells surrounding a lumen in which their secretions accumulate. There can be differentiation among the secretory cells. For example, the *D. melanogaster* male accessory gland includes two visibly distinct secretory cell types – main cells (96% of the cells) and larger, spherical secondary cells, interspersed among the main cells near the distal end of the gland. The two cell types make different, but overlapping sets of products (DiBenedetto *et al*., 1990; Monsma *et al*., 1990; Bertram *et al*., 1992; Wolfner, 1997). Similarly, in *T. molitor*, the male's accessory glands have several lobes, each of which makes a protein of a particular layer of the spermatophore (Grimnes *et al*., 1986). In many cases the secretory cells are themselves surrounded by muscle sheaths whose contraction can cause expulsion of the gonadal gland contents from the gland.

Gonadal glands have evolved in structure and function and these tissues may differ substantially in appearance in different insect and other arthropod groups, varying from secretory epithelia along the wall of the reproductive tract to complicated glandular structures (reviews: Adiyodi and Adiyodi, 1975; Gillott, 1988). Since the origin, structure, biochemistry, and functions of specific glands vary, their classification can be problematic: some glands with different names in different insects probably secrete similar types of substances, and conversely, some glands whose homologies are not certain have been grouped under the same name. Even within one genus, *Drosophila*, different morphologies are seen in some tissues, such as the ejaculatory duct, whose production of glucose dehydrogenase correlates with different morphological duct types seen in the different species (Cavener, 1985, 1987). Interestingly, in addition to modifications of gonadal glands that still preserve a reproductive function, in some cases, derivatives of these glands have been co-opted for other functions. Examples include defensive, or trail-marking functions in ants (review: Blum and Hermann, 1978) or sting apparati in bees and wasps, which are derived from a nonfunctional ovipositor and fed from venom glands that are homologous to certain female gonadal glands (D'Rozario, 1942, cited in Packer, 2003). These modifications have no bearing on reproductive functions and will not be elaborated on here.

1.5.1.4. Development of Gonadal Glands

Insect gonadal glands develop from cells in genital imaginal discs, usually corresponding to abdominal segments A8, A9, and A10 (Sendi *et al*., 1993; Keisman and Baker, 2001; Keisman *et al*., 2001; Christiansen *et al*., 2002). The signals for this development are best understood in *D. melanogaster*. Here, under the influence of sex determination genes (see **Chapter 1.1**) that mediate responses to *decapentaplegic* (*dpp*) and *wingless* (*wg*) signaling pathways, cells in the genital imaginal disc develop into different genital and gonadal gland structures in males and in females. In females, A8 cells normally comprise a large part of the genital primordium and A9 forms only a small part. A8 cells develop into female genital tissues – except for the female accessory glands which develop from A9 cells. In males, the bulk of the genital primordium derives from A9 cells, which ultimately form the internal and external male genital structures, including the male gonadal glands and the ejaculatory duct and ejaculatory bulb. The A8 cells in the male's genital disc form a small tergite, but do not contribute to the gonadal glands in males (see **Chapter 1.1**).

Insect gonadal glands attain their final form in late pharate adults (Chapman and Wolfner, 1988; Sendi *et al*., 1993) and become functionally mature in the adult stage. Hormonal triggers are important in these events. For example, development of the male accessory glands in the migratory locust, *L. migratoria*, is dependent in the presence of juvenile hormones (JHs; see **Chapter 3.7**). Elimination of allatal JH production by ethoxyprecocene, and its recovery after application of a JH analog, supports this model, as does the presence of JH-binding proteins in male accessory glands (Braun

and Wyatt, 1995) and the existence of hemolymph JH-esterases (Paterson and Weaver, 1997) that can modulate JH hydrolysis.

Insects that begin reproducing immediately after the imaginal molt eclose with gonadal glands that appear to be fully differentiated. In contrast, insects with a preoviposition period between ecdysis and reproduction, or those exhibiting adult diapause (see **Chapter 3.12**), exhibit a lag, after which gonadal gland development proceeds from a functionally immature state to complete differentiation (Sturm, 2002). Even if gonadal glands are fully formed at the time of eclosion, a maturation period is required for them to accumulate their full amount of secretion. For example, although *D. melanogaster* males become fertile during their first posteclosion day, it takes 3 days for their accessory gland protein levels to be maximal, and from that point their levels remain stable unless the animal mates (Chapman and Wolfner, 1988; DiBenedetto *et al*., 1990; Monsma *et al*., 1990; Bertram *et al*., 1992). Mating stimulates male accessory gland protein biosynthesis, in a process that also requires JH (Chen, 1984, 1991; Fernandez and Klowden, 1995; Herndon *et al*., 1997; Wilson *et al*., 2003).

Mating can affect the expression of genes in the gonadal glands. For example, during mating of the German cockroach, *Blatella germanica*, formation of the spermatophore and its transfer to the female correlates with the depletion of most of the proteins from the male's accessory glands. The activity of the male's corpora allata (CA) also decreases, indicating that JH production is inhibited during this process (see **Chapter 3.7**). This has been hypothesized to be necessary to allow for a subsequent round of production of secretions by the accessory gland (Vilaplana *et al*., 1996). Consistent with this, following mating and consequent depletion of accessory gland proteins (Acps) in *D. melanogaster*, Acp RNA and protein synthesis are stimulated in the main cells of the male's accessory gland in a process that requires JH (Herndon *et al*., 1997).

1.5.2. Products of Male Gonadal Glands

As shown by the studies noted above, male gonadal glands produce molecules that, upon entry into females, cause post-mating changes in females. In some insects, male gonadal glands also can sequester molecules made in other places in the animal, or can be taken up from the environment (Dussourd *et al*., 1991; Smedley and Eisner, 1995, 1996). These sequestered molecules can be transferred to females during mating along with molecules made in the gonadal glands themselves. In this section, the identities and functions of products made in, or sequestered by, gonadal glands of males are reviewed. First, examples of presumptive nutritive products of molecules transferred from male gonadal glands are presented. The benefit to the donor male in this scenario might be to attract the female, supplement her nutrition, and/or distract her from feeding on him. Second, male-derived products that occlude the female gonopore, thereby contributing to the reproductive success of the male's sperm are described. Third, the presence and contributions of antimicrobial peptides or immune modifiers are discussed. Finally, molecules that influence the behavior or physiology of mated females are described. Although we will discuss many molecules, we are not presenting a comprehensive list. Rather, we have selected examples to illustrate each important aspect of the functions of male gonadal gland products.

An important consideration in the role of male gonadal secretions is their site of action in female insects. With the exception of nuptial gifts, which are consumed orally by the female, male gonadal secretions enter the female through her reproductive tract. This allows them to act from within the reproductive tract, e.g., mating plug proteins (Ludwig *et al*., 1991; Lung *et al*., 2001b), sperm-storage proteins (Bertram *et al*., 1996; Neubaum and Wolfner, 1999a). Experiments, in which effects on females were seen upon transplantation of male gonadal tissues (Garcia-Bellido, 1964; Merle, 1968) and effects of gonadal secretions on levels of JH in mated females (Moshitzky *et al*., 1996; Fan *et al*., 1999a, 1999b, 2000; Eliyahu *et al*., 2003), indicate, that at least some of these proteins must be able to access the hemolymph and affect the neuroendocrine system of the female. Indeed, experiments with *D. melanogaster* have demonstrated that male gonadal secretions enter the circulation of the female shortly after mating (Meikle *et al*., 1990; Monsma *et al*., 1990; Lung and Wolfner, 1999; Lung *et al*., 2002). Seminal proteins enter the circulation through a transiently-permeable section of the vaginal wall (Lung and Wolfner, 1999). Hemolymph entry begins during mating, but rapidly (within minutes) ceases. Inspection of sequences of male proteins that enter the female's circulation in this way has failed to identify a specific primary sequence responsible for targeting. Tertiary structure, or differences in accessibility of male proteins (for example, whether or not they are bound to sperm) may be responsible for their ability to cross this part of the female anatomy to enter the female's circulation.

1.5.2.1. Female Dietary Supplement

Males from many insect species present nuptial gifts to females before or during mating encounters (Vahed, 1998). These gifts are frequently comprised of gonadal secretions associated with transferred spermatophores, and they often include substances of presumptive nutritional value. In many crickets, where such nuptial gifts are common, the male spermatophore is accompanied by a gelatinous material (spermatophylax) upon which the female feeds after mating. Other nuptial gifts are molecules sequestered by, rather than made in, insect gonadal glands. For example, males of some butterfly and moth species exhibit "puddling" behavior, in which they cluster around puddles or damp areas and drink large amounts of liquid. They sequester sodium from this liquid, which they presumably transfer to females during mating (e.g., Arms *et al.*, 1974; Smedley and Eisner, 1995).

Several hypotheses have been proposed for the role of nuptial gifts. They may enhance the number and/or quality of eggs, as described for sodium above. Several elements in addition to sodium have been reported to be transferred to female insects during mating. Phosphorus, transferred to female *D. melanogaster* and *D. nigrospiracula* upon mating, is incorporated into their eggs (Markow *et al.*, 2001), although whether it also provides a nutritional supplement to the female herself is not yet known. Calcium phosphate is transferred to the female in the spermatophore of the butterfly *Calpodes ethlius* (Lai-Fook, 1991), and zinc to the female moth *H. virescens* (Engebretson and Mason, 1980). Nuptial gifts may also provide a dietary supplement that might contribute to female fecundity (this also benefits the male, by enhancing his fitness as a consequence), or may distract the female's attention for a time sufficient for the sperm to be transferred from the spermatophore, or for the male to escape. Of the male gonadal gland proteins transferred to females, many act in the female to modulate behavior, physiology, and sperm storage (see below), but in principle it is also possible that their amino acids provide nutrition to the female as well. There is a trade-off between using nutrients for somatic maintenance and for eggs (e.g., see Salmon *et al.*, 2001); a variety of strategies are used by female insects to allocate nutrients received from their mates to these functions (e.g., see Rooney and Lewis, 1999).

In some cases the main function of nuptial gifts may not be nutritive. While they are consuming nuptial gifts, female insects are distracted from the mating male long enough for him to ensure optimal sperm (or seminal protein) transfer e.g., the spermatophylax of the cricket *Gryllodes sigillatus*, on which the female feeds after mating, lacks nutritive value (Will and Sakaluk, 1994).

Thus, gonadal gland-derived nuptial gifts, and the nutrients they contain, may serve diverse and multiple purposes in insects. There has also been speculation about the role of nuptial gifts in the evolution of female polyandry, by direct nutritional benefit or otherwise (e.g., Kondoh, 2001; Arnqvist and Nillson, 2001). However, detailed consideration of such ecological and evolutionary questions are beyond the scope of this subsection.

1.5.2.2. Components of a Gonopore Plug

During mating, males of many insect species transfer gonopore plugs, or material derived from products of their gonadal glands, which subsequently congeal, and may harden into "plugs" or "masses" within the female reproductive tract. Such structures are assumed to increase the likelihood of paternity in different, but not necessarily exclusive ways (e.g., Patterson and Stone, 1952; Bairati and Perotti, 1970; Duvoisin *et al.*, 1999; Sauter *et al.*, 2001; Brown *et al.*, 2002). Among many possible functions, they may physically obstruct the reproductive tract and thereby interfere with subsequent copulation, indicate that the female has already mated, trap the sperm within the genital tract and thereby prevent sperm backflow, and/or provide a scaffold for sperm movement.

In an example of the first function, male bumblebees (*Bombus terrestris*) transfer a mating plug after they transfer sperm (Duvoisin *et al.*, 1999; Sauter *et al.*, 2001). This sticky plug is digested within the female after several days. Composed of linoleic, oleic, palmitic, and stearic acids (in decreasing order of amount) and of a cyclic dipeptide (cycloprolylproline), it does not contribute components of exceptional nutritional significance to the female (Baer *et al.*, 2000). It is thought that the mating plug may assist in limiting the number of matings by a female. (This is important to increase the average relatedness of workers in a colony – which can positively affect their level of cooperation.) Consistent with this proposed role for the mating plug, the plugs are more rapidly digested in a related bumblebee species (*B. hypnorum*), in which multiple re-matings (as many as six) can occur (Brown *et al.*, 2002). The limited persistence of the mating plug in *B. hypnorum* may permit its re-mating frequency. A similar hypothesis has been proposed in mosquitoes. In *Culex pipiens*, prevention of multiple-mating has been attributed to the formation of a

mucoid plug in the mated female (Bullini *et al.*, 1976).

Experiments in *Drosophila* suggest a similar role for mating plugs and also additional roles in providing a scaffold for sperm movement and a barrier to backflow of sperm (Bairati and Perotti, 1970; Polak *et al.*, 1998). The *D. melanogaster* mating plug is composed of secretions from the ejaculatory bulb that coagulate at the posterior of the uterus, remaining there until being expelled by the first egg deposited after mating. Gels of mating plug proteins show a major band or series of bands, corresponding to electrophoretic variants (Ludwig *et al.*, 1991). This 37 kDa band is an ultraviolet-fluorescent protein called *Drm*-pEB-me; it is encoded by a single gene on chromosome 2 (Ludwig *et al.*, 1991; Lung *et al.*, 2001b). The sequence of pEB-me contains amino acid motifs resembling those in spider silk and mollusc byssal threads (Lung *et al.*, 2001b). The presence of these motifs suggests that self-association of PEB-me might contribute to solidification of the mating plug in the uterus.

In matings in some *Drosophila* species, a more elaborate "insemination mass" is seen to engorge the female's vaginal tissues after mating. This mass is thought to be derived from secretions of female tissues and from sperm and male-derived seminal proteins (Patterson and Stone, 1952). In some cases this mass appears analogous to the mating plug discussed above: it remains soft and is expelled within a few hours of mating. But in other cases, particularly in certain inter-species matings, the mass hardens and remains for days after copulation, e.g., in crosses of *D. buzzati* females with *D. arizonensis* males masses have been seen 192 h post-mating (Patterson and Stone, 1952). The presence of this hardened mass within the female's uterus and oviducts is thought to interfere with sperm storage and/or use, and even with movement of eggs through the oviducts. That interaction between male and female secretions in interspecific matings can result in a hardened, impenetrable, and persistent mass has been suggested to be part of species-isolation mechanisms.

1.5.2.3. Defensive Molecules

Reproductive tracts are (topologically) open to the outside and, thus, potentially subject to microbial invasion. Moreover, the fertilized eggs deposited after a mating are potentially vulnerable to attack by microbes or by animals. Perhaps because of these considerations, gonadal glands make molecules that can potentially defend these reproductive tissues, and gametes, from attack. Male gonadal glands produce several antimicrobial peptides. In *Drosophila* at least four peptides have been detected. Andropin is a 57-amino acid peptide (including its signal peptide) that is related to cecropins. It is made in the male's ejaculatory duct (Samakovlis *et al.*, 1991) and transferred to females during mating (Lung *et al.*, 2001a). Three additional antimicrobial activities were detected as products of male accessory glands (Lung *et al.*, 2001a), but their molecular identity is not known. Whether any of these antimicrobial molecules enter the circulation of the mated female by crossing the wall of the reproductive tract has yet to be determined. Promoter analysis suggests that the antimicrobial peptides drosomycin, attacin, drosocin, and cecropin are expressed constitutively in selected gonadal tissues of *Drosophila* males (as well as females) (Charlet *et al.*, 1996; Ferrandon *et al.*, 1998; Tzou *et al.*, 2002).

Molecules provided from the male can also protect the eggs after deposition. One example occurs in the beetle *Neopyrochroa flabellata*. Male *N. flabellata* ingest cantharidin, and sequester it in their accessory glands. This irritant molecule is then transferred to the female in the spermatophore, later accumulating in the eggs, where its presence protects the progeny from predation (Eisner *et al.*, 1996). Another example involves alkaloids taken up by caterpillars of the moth *Utetheisa ornatrix* and sequestered in the male's reproductive tissues (Dussourd *et al.*, 1988, 1991; Eisner *et al.*, 2000; Rossini *et al.*, 2001). Male moths display modified forms of the alkaloids (hydroxydanaidal) on "brushes" extended from their reproductive tracts. Female moths can thereby assess the relative alkaloid content of their potential mates; males with high alkaloid content are preferred. The alkaloids are transferred to the female during mating and are thought to protect her eggs from subsequent predation. Similarly, in many arctiid moths, pyrrolizidine alkaloids (PA) are among bioactive compounds sequestered from host plants (review: Weller *et al.*, 1999). PA can be transferred from males to females during mating and/or from females to developing oocytes (Hare and Eisner, 1993; Eisner *et al.*, 2000; Rossini *et al.*, 2001), again imparting protection from predation. As with the alkaloids noted above, PA plays a secondary role in mating strategy, since female prefer males with higher levels of PA.

1.5.2.4. Behavioral Modifiers

Molecules made in, or sequestered by, male gonadal glands and transferred to females during mating can affect the females' subsequent behavior. Female attractiveness to males and her reproductive performance (via pheromones and/or behaviors) can be modulated (Blomquist *et al.*, 1995; Jin and Gong,

2001; Jang, 2002), as can her willingness to mate with subsequent courting males (active rejection behavior) (Bastock and Manning, 1955; Garcia-Bellido, 1964; Manning, 1967; Merle, 1968, Chen *et al*., 1988; Hall, 1994; Kubli, 2003).

1.5.2.4.1. Modification of female attractiveness Female moths exhibit a "calling" behavior in which they emit pheromones to attract males, sometimes from a considerable distance. After mating, calling ceases – sometimes permanently – as a result of transfer of gonadal gland products from males. For example, a pheromonostatic peptide (PSP) (*Hez*-PSP-1), produced in the male accessory glands of the moth *H. zea* and transferred to the female during mating, has been isolated and sequenced (Kingan *et al*., 1995). Pheromonostatic peptide prevents activation of the female moth sex-pheromone gland by PBAN (pheromone biosynthesis activating neuropeptide), a cerebral neurohormone whose secretion is environmentally regulated (review: Rafaeli, 2002). Although bio-activity of synthetic *Hez*-PSP-1 was not assayed in the moth *H. zea*, a partial synthetic C-terminal sequence (*Hez*-PSP-135-57) was shown to be pheromonostatic when injected into gravid females of the closely related *H. armigera* (Eliyahu *et al*., 2003).

cis-Vaccenyl acetate (cVA), a lipid that is transferred from male *D. melanogaster* to females during mating, has also been suggested to play a role in modulating female attractiveness in this species. While its gonadal origin (ejaculatory bulb; Butterworth, 1969) is unequivocal, the exact function of cVA is still unclear. It has been suggested that cVA is hydrolyzed in the female to an alcohol by male-derived esterase-6, concurrently transferred during mating (Meikle *et al*., 1990), and that the alcohol serves as a repellent to subsequent mating (Mane *et al*., 1983). This presumptive function may be circumstantial: cVA can be hydrolyzed by this esterase, and topically applied *cis*-vaccenyl alcohol does deter male *D. melanogaster*, but it is not certain that this is one of its functions in the normal mating situation. cVA does function as an aggregation pheromone. Recently, it has been reported that mated females emit cVA on the host fruit, attracting other males and females and inducing aggregated oviposition (Bartelt *et al*., 1985; Wertheim *et al*., 2002).

Another modulator of female attractiveness is methyl salicylate. Topical application of this compound to virgin female moths deters males (Andersson *et al*., 2000). Methyl salicylate can be made from phenylalanine by male moths (*Pieris napi* and *P. rapae*), or taken up from plant hosts and sequestered, and then transferred to females during mating (in *P. napi* and *P. rapae*, in the spermatophore). Marking of mated females by this compound (or related molecules) curtails their mating with subsequent conspecific males. In *P. brassicae*, phenylananine is used by the male to synthesize benzyl cyanide, also called phenylacetonitrile (PAN), which serves a similar anti-aphrodisiac function to methyl salicylate in the other *Pieris* species (Andersson *et al*., 2003). Interestingly, both methyl salicylate and PAN serve other roles in insect chemical communication (Seidelmann *et al*., 2000; Seidelmann and Ferenz, 2002; James, 2003; Ferenz and Seidelmann, 2003; Ninkovic *et al*., 2003); it is intriguing to think that they may have been co-opted for a mating-related function (or vice versa).

1.5.2.4.2. Inducers of rejection behaviors Male gonadal gland products cause females of some insects to actively reject subsequent courting males. For example, *D. melanogaster* females that have mated reject the advances of subsequent males by kicking, running away, and extruding their ovipositor, which physically prevents intromission (reviews: Wolfner, 1997, 2002; Chapman, 2001; Kubli, 2003; Swanson, 2003; and below). Tissue transplantation experiments showed that molecules made by males' accessory glands caused this change in behavior (Garcia-Bellido, 1964; Manning, 1967; Merle, 1968). A 36-amino-acid peptide made by male accessory glands was shown to induce rejection behavior (Chen *et al*., 1988). This molecule, called "sex peptide" (SP, also called *Drm*-SP and Acp70A), was identified by injecting fractions of male accessory gland extracts into unmated females. SP can induce rejection behavior (and increases in egg production) when introduced into the circulation of female flies (reviews: Kubli, 2003; Swanson, 2003; see also Chen *et al*., 1988; Aigaki *et al*., 1991; Soller *et al*., 1999). Recent knockout (Liu and Kubli, 2003) or RNAi knockdown (Chapman *et al*., 2003b) analyses confirmed these functions – but also indicated that SP is not the sole mediator of these phenomena. Indeed, the *D. melanogaster* ejaculatory duct produces a 31-amino acid peptide related to SP, Dup99B (Saudan *et al*., 2002) that can also induce rejection behavior when injected into the circulation of females. Dup99B is transferred to females during mating. However, when males lack Dup99B, their mates still show full changes in receptivity, suggesting that SP plays a larger role in modulating receptivity than does Dup99B. A third regulator of female receptivity, a 27-amino acid peptide (called PS-1) is made by male accessory glands in *D. funebris* (Baumann, 1974a, 1974b; Baumann *et al*., 1975).

In another dipteran, the mosquito *A. aegypti*, "matrone," a complex of two proteins produced by the male's accessory gland, has been reported to modulate post-mating behaviors (Hiss and Fuchs, 1972; Williams *et al.*, 1978).

Synthetic peptides corresponding to parts of SP have been used to show that its rejection-mediating activity derives from the SP's conserved C-terminal 12 amino acids, including a disulfide-bonded region. Although the target site for the SP's action in inducing the receptivity changes is as yet unknown, it binds to many tissues throughout the fly, including the brain (primarily peripheral nerves) and parts of the subesophageal and thoracic ganglia (Ottiger *et al.*, 2000). These binding sites are found in males as well as females, although the peptide can only reach them in mated females. Tethered versions of SP are active when expressed locally in the head, suggesting that access to neural targets may be important for SP function (Nakayama *et al.*, 1997). Blot overlay assays identified different-sized SP-binding complexes in heads and reproductive tracts of flies, suggesting that the former is a receptivity-related receptor while the latter is related to egg-production (Ding *et al.*, 2003). SP binds to sperm in the mated female (E. Kubli, personal communication; Liu and Kubli, 2003). Kubli and colleagues have suggested that such binding could contribute to the long-term effect (Manning, 1967; Kalb *et al.*, 1993) of sperm on receptivity and egg production (Kubli, 1992), if the sperm provided a source for continued release of SP in the mated female. Recent experiments support this hypothesis (Chapman *et al.*, 2003b; Liu and Kubli, 2003).

Interestingly, the same C-terminal region of SP that induces rejection behavior in *D. melanogaster* females causes behavioral changes in female *H. armigera* moths: when synthetic *Drm*-SP (or *Drm*-SP partial peptides) are injected into unmated female moths, PBAN-stimulated female sex-pheromone production is inhibited (Fan *et al.*, 1999b, 2000). This functional cross-reactivity is intriguing: the peptide essentially serves the same purpose (mating inhibition), but in different manners in the two organisms. The effect of *Drm*-SP on *H. armigera*, and that *H. armigera* females normally show inhibition of pheromone production after mating, suggests that *H. armigera* males may produce a functional homolog to *Drm*-SP.

1.5.2.5. Modifiers of the Mated Female's Reproductive Physiology

The physiology of the female is also modified by molecules made in, or sequestered by, her mate's gonadal glands and transferred to her during mating. Levels of egg production by females and the female's hormonal milieu are manipulated by products she receives from her mate's gonadal glands.

1.5.2.5.1. Regulators of the egg-laying process Molecules made by, or sequestered in, the male's gonadal glands and transferred to the female along with sperm have been shown to increase egg production and deposition by mated females. Coupling mating to the initiation of, or increase in, egg production seems advantageous to both sexes. By having males provide the proximate stimulators of egg production, an unmated female need not expend extensive resources on making eggs that will not be fertilized. Having molecules and/or sperm from the male trigger or stimulate egg production means that large numbers of eggs are produced when there are sperm to fertilize them, thus guaranteeing a good supply of fresh eggs for this joint endeavor.

Deposited eggs are the end result of a stepwise "egg-laying process," defined herein based on studies of *D. melanogaster* (Heifetz *et al.*, 2000). The existence of these steps allows separate controls at each level of the process, potentially allowing highest efficiency or guarding against complete disruption of egg production in the event that a single key regulator is absent or disabled. The first of several interdependent steps is the initiation (or completion) of oogenesis. The second step is ovulation, in which oocytes are released from the ovary. Third, the eggs must move down the oviducts. Fourth, they come to rest in the uterus/bursa, where they can be fertilized by sperm released from storage. Finally, the eggs are deposited on the substratum. Although all steps likely occur in all insect reproductive systems, in most cases studies have focused on oviposition (the final step) as a general response. Results from such examples will be discussed below under "oviposition" though the actual locus of the response may be in a prior step or steps.

1.5.2.5.1.1. Oogenesis Oogenesis, the process of egg production by the ovary (see **Chapters 1.2** and **1.3**), involves a series of sequential stages in which the egg initiates and continues meiosis (which then completes or arrests), fills with RNAs and proteins that will support subsequent embryo development, and acquires a vitelline envelope and chorion (eggshell). In unmated females of many insect species, oogenesis is arrested completely, or is delayed at particular stages. In many cases, this arrest is overcome by substances transferred during mating, resulting in an increase in egg deposition.

Control of oogenesis by factors from the male gonadal glands has been well-documented in *Drosophila* (e.g., see Wolfner, 1997, 2002; Hall, 1994; Chapman, 2001; Kubli, 2003 for review). Each *D. melanogaster* ovary (**Figure 1**) contains 16 ovarioles, each of which contains a series of egg chambers at specific, sequential, stages of development. In unmated *Drosophila*, oogenesis ordinarily arrests with a maximum of one mature oocyte per ovariole. There appears to be a "checkpoint" in virgin *Drosophila* females at approximately stage 9 of oogenesis. Mating overcomes this block, allowing oogenesis to proceed. SP injection also overcomes this block (Soller *et al.*, 1997, 1999), indicating that SP is a modulator of egg production (Kubli, 2003).

SP appears to affect egg production in at least two ways. First, *in vitro* studies suggest that SP acts by regulating the levels of JH in *D. melanogaster*: incubation of corpora allata *in vitro* with SP causes increased levels of JHB3 (Moshitzky *et al.*, 1996; see **Chapters 1.3**, **3.6**, and **3.9**). JH is an important regulator of oogenesis in *Drosophila*. Specifically, it regulates the production and uptake of yolk proteins (vitellogenins; made in the fat body and ovarian follicle cells) into oocytes beginning at oogenic stage 7 (e.g., see Riddiford, 1993; Spradling, 1993; **Chapters 1.3** and **3.9** for reviews; also Schmidt *et al.*, 1993; Soller *et al.*, 1997, 1999). Kubli, Applebaum and colleagues have proposed that mating introduces SP into females, which increases JH levels in those females, leading to increased yolk protein levels, and to overcoming the block to oogenesis (Moshitzky *et al.*, 1996; Soller *et al.*, 1997, 1999; Kubli, 2003). The region of SP required for its effects on JH is its N-terminal part (Fan *et al.*, 2000); this differs from the region active in its second effect on egg production and on receptivity (Section 1.5.2.4.2).

The C-terminal region of SP also affects egg production, possibly by acting at another step – expulsion of uterine eggs (Aigaki *et al.*, 1991). This same region of SP induces changes in receptivity behavior, and the same effective concentration of SP is needed for both responses. However, SP binds to at least two different receptor complexes, one in heads and another in female reproductive tracts. This second complex is in the right place to represent a receptor through which SP modulates effects on egg production (Ding *et al.*, 2003). Effects of sperm in keeping oogenesis levels high (e.g., Kalb *et al.*, 1993; Xue and Noll, 2000; Heifetz *et al.*, 2001a) is suggested to result at least in part from SP's binding to, and slow release from, sperm, as discussed above under "receptivity" (Kubli, 1992, 2003; Chapman *et al.*, 2003b; Liu and Kubli, 2003).

As with receptivity, a multitude of male gonadal factors can affect egg production in *Drosophila*. In addition to SP, several other male-derived peptides regulate egg production in various *Drosophila* species, although it is not yet known whether they specifically stimulate oogenesis or the next step, ovulation. Two are relatives of SP. One is *Drm*-Dup99B, the ejaculatory-duct relative of SP noted above to cause receptivity changes upon injection into unmated females (Saudan *et al.*, 2002). Like SP, injection of Dup99B causes increased egg production in *D. melanogaster*, but similar to the situation noted above for receptivity, it appears to play a minor role *in vivo*. *Drosophila biarmipes* males' ejaculatory ducts produce ED-OSS, a 32-amino acid relative of *Drm*-SP (Imamura *et al.*, 1998). Injection of ED-OSS into unmated females stimulates egg production. Two other male – accessory gland-derived molecules that stimulate egg production in *Drosophila* species have been found by injection-fractionation assays, but little is known of their detailed structure, or the steps at which they act. PS-2 is a glycine carbohydrate derivative from *D. funebris* with egg-production stimulatory activity (Baumann, 1974b, 1974a, Baumann *et al.*, 1975), and OSS from *D. suzukii* also has this activity (Ohashi *et al.*, 1991).

A similar molecular basis may modulate oogenesis after mating in heliothine species of noctuid moths. In these insects, mating induces oogenesis from a completely arrested state. As in *Drosophila*, oogenesis, including choriogenesis, in heliothine moths is regulated by JH (Ramaswamy *et al.*, 1990; Satyanarayana *et al.*, 1992; reviewed in **Chapter 1.3**). JH titers in the hemolymph of mated *H. virescens* females are significantly higher compared to titers in virgin females (Zeng *et al.*, 1997). Elevation of JH production by male-derived accessory gland factors in heliothine noctuid moths would explain the high egg production in mated females. Interestingly, injection of *Drm*-SP into *H. armigera* causes an increase in egg production and JH levels consistent with the presence and action of a related molecule in this moth (Zeng *et al.*, 1997); as for *D. melanogaster*, the N-terminal region of *Drm*-SP induces JH production when injected into unmated *H. armigera* females (Fan *et al.*, 2000). These findings are consistent with the postulate in Section 1.5.2.4.2, above, that *H. armigera* males may produce and transfer to their mates a functional homolog of *Drm*-SP. In another parallel between *D. melanogaster* and *H. armigera* females' responses to male gonadal gland products, it appears that there may be multiple male-derived molecules in *H. armigera*, each of which can increase egg

production. In addition to the likelihood that *H. armigera* possesses a functional homolog of *Drm*-SP, male accessory glands of this moth also produce proteins of larger molecular masses (55–66 kDa) that affect reproductive maturation (oogenesis and egg deposition) in female *H. armigera* (Jin and Gong, 2001).

1.5.2.5.1.2. Ovulation Ovulation is the process by which an egg is released from the ovary. As such, its rate is limited by the rate of oogenesis, though it can in theory feed back to regulate oogenic rate by controlling the rate at which mature oocytes leave the ovary and hence the feedback controls. In *Drosophila* (Heifetz *et al.*, 2001b), and probably Hymenoptera (Went and Krause, 1974), ovulation also causes oocytes to activate, meaning that they resume meiosis, initiate translation, alter the cross-linking state of their vitelline envelope, and essentially transition into a state that is competent to initiate embryonic development.

In mated *D. melanogaster* females, ovulation is stimulated by male gonadal gland proteins received during mating. In particular, a 264-amino acid prohormone called Acp26Aa (or ovulin, *Drm*-Acp26Aa), from the male's accessory glands, stimulates ovulation. Ovulation is not fully stimulated in females that had mated to mutant males that do not produce Acp26Aa (Herndon and Wolfner, 1995; Heifetz *et al.*, 2000); that ovulation, specifically, is dependent on Acp26Aa was determined by assessing the efficiency of each stage in the egg production process in these females (Heifetz *et al.*, 2000). Unmated females engineered to express Acp26Aa on their own ovulate at elevated levels (Y. Heifetz, L.N. Vandenberg, H.I. Cohn, and M.F. Wolfner, in preparation), confirming the role of Acp26Aa in this process. Its normal action has been suggested to be to "clear" old eggs from ovaries, which also ultimately allows egg production to be coordinated with release of sperm from storage (Chapman *et al.*, 2001). Although Acp26Aa's sequence is variable across and within species (see Section 1.5.4 for discussion), a short sequence within one of its active regions is similar to that of egg-laying stimulatory hormones in the mollusc *Aplysia californica* that stimulate muscular contractions and behavioral changes, thus causing egg release (Scheller *et al.*, 1982; Kaldany *et al.*, 1985; Rothman *et al.*, 1986; Monsma and Wolfner, 1988; Heifetz *et al.*, 2000). The mollusc egg-laying hormones (califins, ELH), are cleaved from a prohormonal precursor, and Acp26Aa undergoes comparable proteolytic processing upon entry into female *D. melanogaster* (Monsma and Wolfner, 1988; Monsma *et al.*, 1990; Park and Wolfner, 1995).

Like most male accessory gland proteins in *D. melanogaster*, about 1/3 of a male's Acp26Aa is transferred to his mate (Monsma *et al.*, 1990). Transfer begins early (~3 min into a 20 min mating, before sperm start being transferred) and is largely complete by mid-mating. Once in the female, Acp26Aa targets to the base of the ovary (Heifetz *et al.*, 2000), and also enters the female's circulation (Monsma *et al.*, 1990). The region to which it targets at the ovary base is one at which changes occur in vesicle release and neuromodulator levels after mating (Heifetz and Wolfner, 2004; Y. Heifetz and M.F. Wolfner, unpublished data), suggesting the triggering, by mating, of muscle contractions that move the egg from the ovary into the oviducts. The targeting of Acp26Aa into the circulation gives it access to the neuroendocrine system, from which it could also modulate ovulation.

1.5.2.5.1.3. Egg deposition As noted earlier, in many insects oviposition has been used as a measure for the entire egg laying process. Several regulators of egg deposition that are products of male gonadal glands are discussed below. It is not yet known whether they directly modulate the efficiency of deposition of eggs onto the substratum, or regulate a step leading up to it.

Among Orthoptera, male gonadal glands have been shown to provide some stimulators of egg deposition. For example, the accessory glands of male migratory locusts (*L. migratoria*) produce a myotropic peptide that exhibits potent activity on the oviduct of conspecific females and cross-reactivity on the oviduct of the cockroach, *Leucophaea maderae* (Paemen *et al.*, 1991). It is proposed to stimulate oviposition, though the details of its action are as yet unknown. In migratory grasshoppers, *M. sanguinipes*, an oviposition-stimulating protein (OSP) is produced in the long hyaline tubules of the male's accessory glands. OSP is composed of two subunits with combined molecular mass is about 60 kDa (Yi and Gillott, 1999). When applied to the oviduct, it stimulates an increased frequency of oviduct contraction (Yi and Gillott, 2000).

1.5.2.5.2. Modifiers of hormonal levels in females An important way by which male gonadal gland secretions modulate the responses of mated females is by modulating the female's hormonal levels. Given the important roles of JH in female reproductive physiology (see above; **Chapters 1.3** and **3.9**), an effective way for the male to modulate his

mate's hormonal levels is to transfer to her JH or modulators of JH levels. This is accomplished in several ways in the insect world.

For example, the corpora allata (CA) of adult male saturniid moths, *Hyalophora cecropia*, synthesize JH acids which are then taken up by their accessory glands and methylated therein to JH-I and JH-II. Male accessory gland-derived JH-I and JH-II are subsequently transferred to the female reproductive tract during mating (Shirk *et al.*, 1980). The possibility exists of a similar strategy in the grasshopper *M. sanguinipes*. Extracts of male accessory glands, when injected into reproductively mature virgin females, induce oviposition a day later, similar to the effect of mating (Friedel and Gillot, 1976). A high-affinity JH-binding protein (see **Chapter 3.7**) with molecular mass of 40 kDa is present in the long hyaline tubules of accessory glands of male *M. sanguinipes* (Ismail and Gillott, 1994). Since JH-binding proteins facilitate the transport of JH, it is tempting to speculate that these proteins cause the sequestration of humoral JH into the accessory glands, allowing its transfer to females during mating and thus causing a stimulation of oogenesis.

In another strategy, several homologs of JH are synthesized *de novo* in the male accessory glands of the mosquito *A. aegypti* (Borovsky *et al.*, 1994). JH is necessary for oocytes to advance beyond an early (teneral) stage in development in nutritionally-deprived *A. aegypti* females. Topical application of JH to such females can bypass this arrest (Klowden and Chambers, 1991), as can implantation of a male accessory gland or injection of male accessory gland homogenates – presumably because they provide JH. Upon mating, then, a female can receive JH to mature her ovarian follicles to a stage competent to deposit yolk (yolk deposition requires that the female have taken a blood meal). A maturational change analogous to that occasioned by exogenous provision of JH (e.g., from the male) occurs following a sugar meal (Feinsod and Spielman, 1980); this meal apparently provides a way for the female to elevate her own production of JH, providing an alternative strategy to achieve a hormonal milieu supportive of further ovarian development.

As noted earlier (Section 1.5.2.5.1.1), *Drm*-SP can elevate JH levels in *D. melanogaster* CA incubated *in vitro*, leading to the suggestion that SP carries out a similar function *in vivo*, thereby stimulating oogenesis (Moshitzky *et al.*, 1996; Soller *et al.*, 1997, 1999). Studies of the effects of *Drm*-SP on *H. armigera* have suggested that male *H. armigera* might transfer a molecule related to *Drm*-SP that could increase JH levels in their mates (Fan *et al.*, 1999a, 1999b, 2000). Specifically, the CA of newly emerged *H. armigera* adults are functionally immature and require a day after eclosion to fully acquire competence to produce JH; this maturation can be hastened by addition of *Drm*-SP to the incubation media. At least the first five N-terminal amino acid residues of *Drm*-SP are essential for CA stimulation in both *Drosophila* and *Heliothis* (Fan *et al.*, 2000), whereas *Drm*-Dup99B, which differs from *Drm*-SP in its N-terminal region, does not cause allatal stimulation.

1.5.2.6. Mediators of Sperm Transfer, Storage, and/or Sperm Competition

Female insects store sperm after mating. For example, *D. melanogaster* females receive ~4000–6000 sperm in a mating and store ~1000 of these. *Drosophila melanogaster* females use up to ~50% of the sperm they have stored to fertilize eggs (see Gilbert, 1981; Neubaum and Wolfner, 1999b; Bloch Qazi *et al.*, 2003 for review). Insect sperm are stored in specialized organs (seminal receptacles and/or spermathecae; **Figure 1**) that branch out from the oviducts and bursa/uterus. The walls of these organs themselves (especially spermathecae) and/or glands in the female associated with these organs (e.g., female accessory glands, spermathecal glands) are thought to produce molecules that assist the sperm in staying viable in storage (see Section 1.5.3.2, below).

Storage of sperm by mated females is important for several reasons (see Neubaum and Wolfner, 1999b; Bloch Qazi *et al.*, 2003 for review). First, it gives a mated female an abundant supply of sperm with which to fertilize her eggs, even when males are not plentiful. Second, it allows the male's (as well as female's) progeny to be produced over a long period, which can provide some protection if conditions immediately following mating are not conducive to progeny or egg production. Third, the persistence of several post-mating behaviors is dependent upon the presence of sperm. As noted earlier, one mechanism for this has been suggested to be the binding to, and gradual release from, the sperm of male-derived gonadal gland products (Kubli, 1992; Liu and Kubli, 2003; Swanson, 2003). The sperm's role in prolonging behavioral effects after mating seems most obviously advantageous to the male in preventing his mate from additional mating. However, it also can be advantageous to the female, by allowing her to avoid costs of mating (see Section 1.5.4.2.1) including increased exposure to pathogens or toxic proteins transferred during the mating, risk of predation, and loss of foraging time. Finally, the storage of sperm by female insects, and the fact that many insects mate more than once despite the decreased propensity to mate after a first mating, can be an important

selective process. Specifically, there can be competition between the sperm of different males (Parker, 1970) or, alternatively, the female can exert choice (preference) to select for use the sperm of a more advantageous male (Eberhard, 1996).

In some insects, secretions from male gonadal glands are required (or presumably required) for transfer of sperm to the female. For example, in *T. molitor*, Happ and colleagues have shown that different portions of the male beetle's accessory gland synthesize proteins of different layers of the spermatophore, the structure in which sperm are transferred to females during mating (Grimnes *et al*., 1986). In another example, proteins made by conglobate glands (also called phallic glands; these glands are associated with the reproductive tracts of male *B. germanica*) have been suggested to contribute to the formation of the spermatophore by these male cockroaches. This suggestion is based on the temporal pattern of accumulation of these proteins, as well as the effect of JH on their accumulation and on reproductive maturation (Vilaplana *et al*., 1996). A role for male gonadal gland secretions in sperm transfer may not be universal, however. In *Drosophila* (a nonspermatophore-using insect), secretions of the male's accessory gland are not required for sperm transfer (Tram and Wolfner, 1999; Xue and Noll, 2000), although actions of products of other gonadal glands in this process have not been tested.

Even after sperm have been transferred to females, their dynamics can be affected by male gonadal gland secretions that were transferred with them. For example, experiments in *Drosophila* showed that the products of male reproductive tissues are important for sperm storage, utilization, or competition. The role of gonadal gland products in sperm storage is demonstrated by the severely impaired levels of storage of sperm transferred to *D. melanogaster* females in the near absence of male accessory gland proteins (Kalb *et al*., 1993; Tram and Wolfner, 1999). Two experiments demonstrated the role of male gonadal gland products in the utilization of stored sperm. First, female *D. pulchrella* mated to males of a different but related species of *Drosophila* had few or no progeny, but progeny-production could be rescued to some extent by injecting the females with extracts of reproductive organs from their conspecific males (Fuyama, 1983). Second, *D. melanogaster* females mated to males without accessory glands did not produce progeny until they were post-mated with (spermless) males that could provide accessory gland products (Xue and Noll, 2000). The role of gonadal gland proteins in sperm competition is shown by differences in sperm competition levels in matings with or without accessory gland function (Harshman and Prout, 1994) and by the association of alleles of some accessory gland protein genes with levels of sperm competitive ability (Clark *et al*., 1995).

Several *Drosophila* male gonadal gland products have been suggested to play a role in sperm storage. *Drm*-Acp36DE, a 912 amino acid novel glycoprotein produced in *D. melanogaster* male accessory glands, is essential for sperm storage by mated females (Wolfner *et al*., 1997; Neubaum and Wolfner, 1999a). Acp36DE enters the female's sperm-storage organs and binds to sperm; it does not enter the female's circulation (Bertram *et al*., 1996; Neubaum and Wolfner, 1999a; Bloch Qazi and Wolfner, 2003). Within the female's reproductive tract it also localizes to the anterior end of the mating plug, near the openings of the storage organs, and along the wall of the oviduct just above the openings of the sperm storage organs. Without Acp36DE, sperm are stored poorly (only ~10–15% as many as normal are stored; Neubaum and Wolfner, 1999a); similar to the number that are stored in the absence of all Acps (Tram and Wolfner, 1999), and post-mating effects that depend on stored sperm do not persist (Neubaum and Wolfner, 1999a). Acp36DE is needed to get sperm into storage, but not to maintain them there or release them from storage (Neubaum and Wolfner, 1999a; Bloch Qazi and Wolfner, 2003). The presence of Acp36DE from a prior mating appears to help subsequent sperm resist competition (Chapman *et al*., 2000).

These findings have led to several models for action of Acp36DE, involving corraling of sperm into a storage site, forming a trellis along which sperm can move, triggering changes in the storage organs that pull, or attract, sperm into them, or assisting sperm in bundling or in moving along a "trail" into storage (Bertram *et al*., 1996; Neubaum and Wolfner, 1999a; Bloch Qazi and Wolfner, 2003). Variation in sperm competition levels in wild caught *D. melanogaster* strains correlates with allelic variation at Acp36DE and four other genes encoding male accessory gland proteins (Acp26Aa/Ab, Acp29B, Acp53E, and Acp76A) (Clark *et al*., 1995). This suggests that the male proteins produced from all these loci may play important roles in the dynamics of sperm after transfer to the female. One additional male accessory gland protein, the protease inhibitor Acp62F, localizes to the sperm storage organs of a mated female. It has thus been suggested to contribute to the regulation of the proteolytic environment surrounding the sperm, and thereby to contribute to the activation of sperm or, alternatively, to protecting their surface

proteins from proteolysis (Lung *et al*., 2002). Finally, two products of the ejaculatory duct, esterase 6 and glucose dehydrogenase – also produced in the ejaculatory bulb (Cox-Foster *et al*., 1990) – have been suggested to play roles in sperm dynamics in mated females (Gromko *et al*., 1984; Iida and Cavener, 2004).

1.5.2.7. Modification Enzymes

Seminal fluid in insects, as in mammals, is rich in proteases (Swanson *et al*., 2001; Mueller *et al*., 2004) and protease inhibitors (Schmidt *et al*., 1989; Lung *et al*., 2002; Swanson *et al*., 2001; Mueller *et al*., 2004). Trypsin inhibitors have been identified among accessory gland proteins in *D. funebris* (Schmidt *et al*., 1989) and *D. melanogaster* (Lung *et al*., 2002), and six others are predicted by bioinformatic criteria (Swanson *et al*., 2001; Mueller *et al*., 2004); at least two (*Drm*-Acp62F and the predicted serpin *Drm*-Acp76A) are known to be transferred to the female during mating (Coleman *et al*., 1995; Wolfner *et al*., 1997; Lung *et al*., 2002). Six proteases also are predicted to be produced in, and secreted by, the male's accessory gland, based on EST screening and bioinformatic analysis (Swanson *et al*., 2001; Mueller *et al*., 2004). The roles of these enzymes have not been established, but several models have been proposed for their function, based in part on studies in mammals (He *et al*., 1999; Murer *et al*., 2001). These include action in, or regulation of, proteolytic cascades that activate or protect sperm, or prohormones, and protection of the female reproductive tract. Interestingly, at least one protease inhibitor (the *D. melanogaster* male-derived *Drm*-Acp62F) also enters the circulation of the female (Lung and Wolfner, 1999). Its presence there may be, counterintuitively, harmful: ectopic expression of this protein such that it is present in the circulation causes toxicity to *D. melanogaster* (see Section 1.5.4.2.1). Other modification enzymes found or predicted among the secretion of male gonadal glands include acid lipase activity found in the *D. melanogaster* male accessory gland (Smith *et al*., 1994), and at least six lipases predicted bioinformatically to be expressed in male accessory glands (Swanson *et al*., 2001; Mueller *et al*., 2004). Functions of these molecules are unknown, but they may provide an energy source for sperm.

1.5.3. Products of Female Gonadal Glands

Products derived from female gonadal glands are known or believed to play a variety of roles in fertility. These include facilitating the passage of eggs through the reproductive tracts, modulating the storage or maintenance of sperm, contributing to reproductive structures such as hardened plugs or hardened and tanned egg cases that place and protect eggs subsequent to deposition, and defending the reproductive tract or gametes from attack by microbes or other organisms. Products of female gonadal glands can also elicit long-term behavioral effects on filial generations (e.g., McCaffery and Simpson, 1998). Finally, female gonadal glands of certain hymenopterous parasitoids appear to produce substances that compromise their host's development or immune systems. These roles are discussed below.

Less is known at the molecular level about female gonadal gland secretions, as compared to male gonadal gland secretions. However, the positions of female gonadal glands can sometimes provide an indication of the likely functions of their products in reproduction. Gonadal glands located near the ovary likely produce secretions that facilitate the passage of eggs through the reproductive tract, and possibly the activation of those eggs. Gonadal glands located near the exterior opening of the reproductive tract are likely to be the source of molecules that coat the egg surface, or construct pods in which eggs are deposited. Products of gonadal glands located between these two regions likely facilitate the passage of sperm or eggs through the oviducts, and may also function in aiding sperm storage, and/or facilitate sperm-egg interaction.

1.5.3.1. Lubrication of Female Reproductive Tract

Three reproductive processes are likely to require lubrication of the insect female's reproductive tract. In each case a role for secretions of female gonadal glands has been postulated or demonstrated, although the biochemical nature of the lubricants has not yet been determined. First, lubrication may be needed to support the act of copulation. Such lubrication is one of the functions proposed for the secretion of female accessory glands of the yellow dung fly *Scathophaga stercoraria* (Hosken and Ward, 1999). Second, a supportive medium must be available to assist sperm in transiting through the uterus and oviducts into storage, and from storage into sites for fertilization. In addition, the composition and the viscosity of the medium could facilitate or inhibit sperm movement (Yanagimachi and Bhattacharyya, 1988; Moore *et al*., 2002). Given the location of the openings of the ducts of the female accessory glands (alternatively termed colleterial glands or parovaria) – close to

the sperm storage organs – it seems likely that these glands supply secretions that assist sperm movement within the oviduct and into storage. Studies in Lepidoptera, such as noctuid moths, support the idea that female accessory gland secretions provide lubrication that assists sperm movement through the reproductive tract into the spermathecal duct (Callahan and Cascio, 1963). Third, the smooth passage of an egg from ovary to deposition on the substratum is likely to be assisted by lubrication from secretions from female gonadal glands that facilitate movement of the large egg through the narrow-diameter oviducts and ovipositor. For example, in the cricket *T. commodus*, proteinaceous secretions from the female accessory glands accumulate after adult ecdysis, with kinetics that correlate with increased egg-deposition activity. These secretions have thus been suggested to function as a lubricant facilitating passage of eggs through the narrow ovipositor (Sturm, 2002). Similarly, proteinaceous secretions of female accessory glands (cement glands) have been suggested to play a lubricating role in the female *Rodnius prolixus* (Lococo and Huebner, 1980).

1.5.3.2. Maintenance of Sperm Viability and "Quality"

When they enter the female, sperm are in a male-provided supportive environment. However, once in the female, their continued survival likely depends on female-supplied molecules. After transfer to the female reproductive tract, sperm are retained in most insects in the sperm storage organs (spermathecae, seminal receptacles). Some of these organs appear to have secretory capacity (e.g., often, spermathecae); others are associated with secretory glands (e.g., spermathecal glands), producing lipoproteins, phospholipids, carbohydrates, and proteins (Davey and Webster, 1967; Bhatnagar and Musgrave, 1971; Filosi and Perotti, 1975; see Gillott, 1988). The secretions of these tissues may support the viability of stored sperm (Anderson, 1945) and help to maintain the sperm in an optimal state that maximizes their fertilization potential.

Several aspects of the storage situation could impact the viability or "quality" (fertilizing potential) of the sperm. First, as suggested from studies in non-insect systems (Visconti *et al*., 2002; Hirohashi and Vacquier, 2003), the ionic environment may be important. Female gonadal tissues have been suggested to assist in providing a supportive ionic environment in the honeybee *A. mellifera*. Spermathecal fluid of *A. mellifera* includes ions such as K^+, Na^+, Ca^{2+}, H^+, Cl^-, PO_4^{3-} (Gessner and Gessner, 1976). The ultrastructure of honeybee spermathecal glands suggest that they play a role in ion transport to maintain a physicochemical environment conducive to sperm viability (Kressin *et al*., 1996). In addition to providing a supportive ionic environment, other components of the gonadal glands might help to provide an optimal environment for sperm survival or maintenance. This role has been suggested for glucose dehydrogenase (Gld), given its expression in the female's sperm-storage organs (seminal receptacle and spermathecae) as well as the female accessory glands (Cox-Foster *et al*., 1990; Keplinger *et al*., 1996, 2001; Iida and Cavener, 2004).

Second, secretions of female gonadal tissues might provide energy sources for sperm motility and metabolism. Energy sources for sperm motility are likely initially provided by the male secretions that accompany the sperm into the female. Subsequently, the female must provide such molecules. For example, honeybee spermatozoa rapidly oxidize free sugars of the seminal plasma (Blum *et al*., 1967) and thereafter require a replacement energy source that may be provided by epithelial cells of the female spermathecal ducts. Dense aggregates of glycogen are found at the basal side of these cells in non-ovipositing queen bumblebees. Once egg deposition starts, the glycogen stores gradually move towards the apical side of the epithelium cells. Moreover, bumblebee spermatozoa metabolize glucose as an energy source shortly before fertilization (Seth *et al*., 2002), and sugars are present in the spermathecal duct of the bumblebee queen. In addition to energy-rich substrates, other contributors to sperm metabolism are provided by female gonadal glands. For example, in the tomato moth *Lacanobia oleracea*, angiotensin I-converting enzyme (ACE) activity is found in the male accessory glands, and in the spermatheca/bursa copulatrix of the female (Ekbote *et al*., 2003); some of the activity in the female may have been transferred from the male, but some is endogenous. It appears that the spermatophore/bursa copulatrix of mated females also produces an aminopeptidase, a carboxypeptidase, and a dipeptidase. The authors hypothesized that these peptidases might be involved in the breakdown of proteins from the spermatophore. Perhaps this could assist sperm motility. Since ACE activity is also high in the spermatheca, it is possible that ACE mediates proteolysis of energy sources in the spermatheca. Female accessory glands of the sand fly, *P. papatasi* contain significant lipase activity. A major protein component of their secretion is a lipase-like protein (*P. papatasi* lipase – *Phpa*-LIP) that shares a sequence similarity with mammalian lipases, including the presence of conserved catalytic residues (Rosetto *et al*., 2003a). Perhaps *Phpa*-LIP

might function in the utilization of male derived lipids that are transferred to females during mating, as suggested for *Drosophila* (Smith *et al.*, 1994). This, in turn, could provide an energy source for sperm, as well as, potentially, modifying the sperm to increase their fertilizing efficiency. Thus, by regulating the ionic environment and providing energy sources, female gonadal glands may assist in keeping sperm viable and motile when in storage.

1.5.3.3. Modulating Sperm–Egg Interaction

In addition to promoting the movement of gametes to sites where they could meet (Section 1.5.3.1), female gonadal gland secretions could promote sperm–egg interaction by modifying the sperm or egg to facilitate the penetration of the egg by the sperm. Three examples are consistent with such action.

Studies on the housefly *M. domestica* suggest that female accessory glands' products may modify the egg to allow more efficient penetration by sperm (Leopold and Degrugil, 1973). If the accessory glands are removed from mated female houseflies, the females' fertility is reduced to less than 1% of normal. Eggs deposited by these females rarely contain sperm, suggesting that female accessory gland secretions were needed either to allow sperm to reach the site of egg penetration or to penetrate the eggs. Subsequent work indicated that the secretion is involved in the disintegration of the micropylar cap of the egg (Degrugillier and Leopold, 1976; Leopold *et al.*, 1978; Degrugillier and Grosz, 1981), which could facilitate sperm entry. This dissolution of the micropylar cap is likely the result of hydrolytic enzymes produced in the female's accessory gland. Esterases, amidase, and trypsin-like activity have been found in this tissue (Leopold, 1981; Judd *et al.*, 1983). These enzymes also could potentially play a role in activating proteins on the sperm surface.

Female accessory gland products, such as two β-*N*-acetylhexosaminidase isoenzymes (HEX1 and HEX2) reported in *C. capitata*, have also been suggested to modify proteins on the micropyle's surface, perhaps to improve the binding of sperm to the micropyle (Marchini, 1989). Specific lectin binding sites are seen on the *C. capitata* egg's micropylar cap, at different stages in the egg production process (Dallai *et al.*, 1986). A lectin, *Dolichos biflorus* agglutinin, that is specific for terminal *N*-acetylhexosaminyl residues reacts with mature eggs obtained from ovaries but not with deposited eggs. It is possible, but not proven, that enzymes made by the female gonadal glands could mediate this change in micropylar surface sugars, perhaps to control the ability of sperm to penetrate the eggs.

1.5.3.4. Egg Protection – Physical Barriers

Secretions from female gonadal glands contribute to protective structures that enclose the eggs deposited by certain types of female insect and/or assist in inserting or attaching the eggs to the substratum.

Examples of protective structures include the egg-cases (oothecae) that enclose cockroach eggs and protect them from desiccation, predation, and parasitization. Depending on the biology of the cockroach species, females deposit egg-cases soon after they are produced, carry the egg cases protruding from their genitalia for a while prior to deposition, or carry the cases around until the neonate larvae hatch (Stay and Roth, 1962; Willis and Brunet, 1966; Adiyodi, 1968; Gillott, 1988). Egg cases are composed of structural proteins synthesized in the female accessory glands. When newly-formed, these egg-cases consist of a sticky substance, which hardens rapidly, and then tans (see **Chapter 4.4**). Female accessory glands of several cockroaches (e.g., *Periplaneta australasiae*, *B. discoidalis*) contain 3,4-dihydroxybenzoic acid (DOBA), which is thought to participate in the tanning process (Kramer *et al.*, 1991; Hopkins *et al.*, 1999). In *Nauphoeta cinerea*, a viviparous cockroach, two protein fractions from the left female accessory gland comprise the major structural proteins of the egg case. Their appearance and accumulation correlates with the time of ootheca formation. These proteins accumulate in females with maturing ovaries, and are absent, or present only in trace amounts, in post-ovulating females (Adiyodi, 1968). Reproductive cues also appear to regulate protein production in the left accessory gland of other cockroaches and in two cases, JH, or at least the CA, have been shown to stimulate the production of oothecal protein (*B. germanica*, Burns *et al.*, 1991; *P. americana*, Willis and Brunet, 1966).

Locust and mantid female accessory glands produce a foamy secretion that forms a protective sheath encasing the egg batches deposited by the female in the soil. Egg batches of the desert locust *S. gregaria* are embedded in an egg pod that is capped by hardened foam. The foam is derived from viscous proteinaceous material produced by the female accessory glands and lateral oviducts (Szopa, 1981). Components that induce tanning of the foam are produced in female gonadal glands. For example, the median glandular pouch, positioned near the posterior opening of *S. gregaria* oviduct, may produce a component involved in the frothing of the proteinaceous material (Szopa,

1981). Similarly, the female accessory (Comstock-Kellog glands) of the grasshopper *Romalea guttata* produce material that tans the eggs and hardens the froth in which the eggs are embedded (Eisner *et al*., 1966). Lastly, the female accessory glands/calyx of the grasshopper *M. saguinipes* produce catechols that participate in the process of tanning. DOBA and its precursor 3,4-dihydroxyphenylalanine (DOPA), respectively, are the major and minor catechols produced in the female accessory glands of females with fully developed eggs. Young females with undeveloped eggs or females that had recently oviposited have little or no DOBA (Hopkins *et al*., 1999).

In many insect species, ovipositing females attach their eggs to the substratum. Female accessory glands of these insects secrete adhesive material, including adhesive proteins and also, at least in *Chrysomya putoria* flies, polysaccharides, mucoproteins, and glycoproteins (Tirone and Avancini, 1997). The adhesive pastes the eggs, egg case, or ootheca to the substratum. The importance of the role of the accessory glands in producing this glue can be seen in the saturniid moth *Antheraea mylitta*. If accessory glands are removed from female moths just after mating, the moths deposit only "loose" eggs (e.g., not pasted to the substratum) (Chaudhuri and Sinha, 1994). The egg deposition rate in these moths is faster, presumably because there are no viscous glue proteins to slow the passage of loose eggs through the oviducts.

1.5.3.5. Egg Protection – Antimicrobial Molecules

As noted earlier (Section 1.5.2.3), during copulation and thereafter in the mated female reproductive tract, deposited eggs and stored sperm are potentially subject to microbial attack and, in the case of deposited eggs, also to attack by other organisms. In addition to antibacterial/antimicrobial/protective agents donated by the male in seminal fluid, molecules made in female gonadal glands can protect the female reproductive tract, gametes, or deposited eggs from infection or parasitization. Some of these molecules appear to be made constitutively in females, providing continual protection for a reproductive tract that is topologically open to the exterior.

For example, *C. capitata* female accessory glands produce at least four antibacterial peptides called ceratotoxins. Although eight distinct ceratotoxins gene sequences have been identified in *C. capitata* or in *C. rosa* (Marchini *et al*., 1995; Rosetto *et al*., 1996, 1999, 2003b), only four mature peptides (ceratotoxin A, B, C, and D) have been isolated in *C. capitata* (Rosetto *et al*., 1997). Ceratotoxins A, B, and C are effective against Gram-negative and Gram-positive bacteria and have lytic activity against human erythrocytes (Marchini *et al*., 1993; Rosetto *et al*., 1996, 2000). Ceratotoxins have sequence and structural similarities to other insect antimicrobial peptides such as cecropins and melittin (Boman and Hultmark, 1987), and to the amphibian defense peptide magainins and dermaseptin (Bevins and Zasloff, 1990; Nicolas and Mor, 1995). The production of ceratotoxins specifically expressed in glands of sexually mature females is enhanced by mating and modulated by JH (Marchini *et al*., 1995; Rosetto *et al*., 1996). Since ceratotoxins were found on the surface of deposited eggs, Marchini *et al*. (1991, 1997) hypothesize that the antimicrobial material delivered by the egg to the egg deposition site can block the attack of microbial agents and thus create an environment that increases the survival of eggs and larvae. Several antimicrobial peptides are also produced in *Drosophila* female reproductive tract tissues – cecropin, defensin, and drosomycin in the sperm-storage organs, and drosocin in the oviduct and ovarian calyx of *Drosophila* (Charlet *et al*., 1996; Tzou *et al*., 2002). However, to date none have been reported to be produced in female accessory glands.

1.5.3.6. Chemical Marking

Molecules produced by female gonadal glands can be placed onto the substratum, not only onto the surface of the deposited egg as in the case discussed in the above section. Once on the substratum these molecules can potentially exert effects, such as oviposition-deterrence or host-marking, phenomena seen in many phytophagous insects, e.g., the cigarette beetle, *Lasioderma serricorne* (Kohno *et al*., 1986; Imai *et al*., 1990); the cabbage seed weevil, *Ceutorhynchus assimilis* (Ferguson and Williams, 1991; Mudd *et al*., 1997); the orange-tip butterfly, *Anthocharis cardamines* (Dempster, 1992); and many tephritid flies (Straw, 1989). It has been suggested that such marking and subsequent avoidance of egg deposition sites by subsequent females can increase the survival rate of eggs deposited by a female (Anbutsu and Togashi, 2001).

In the Japanese pine sawyer, *Monochamus alternatus*, the spermathecal gland of females produces a jelly-like secretion that is deposited on oviposition sites. This secretion contains semiochemicals that deter conspecific females from depositing eggs at the same site (Anbutsu and Togashi, 2001). Similar mechanisms may be used by other insects, including some for which the semiochemicals originate from other reproductive organs, e.g., ovaries (Prokopy

et al., 1976; Zimmerman, 1979); or female accessory glands (Schoonhoven, 1990).

1.5.3.7. Behavior Modification

Female gonadal gland secretions can participate in mediating the post-mating changes that are triggered, when females receive substances from male gonadal glands. For example, a sensory bristle at the distal end of the spermathecal duct in female grasshoppers (*Gomphocerus rufus*) appears to function in signaling females to be nonreceptive. This signaling is triggered by mating, and specifically by secretions that the females receive from their mates' accessory glands' white secretory tubule 1 (WS), and that enter the female's spermathecal duct (Hartmann and Loher, 1996). Hartmann and Loher (1999) hypothesized that the WS proteins function as carriers of small molecules that are thus brought into the spermathecal lumen. Female-provided proteases, secreted from the spermathecal gland cells (Hartmann and Loher, 1999), are then hypothesized to liberate these small molecules, which then stimulate chemoreceptors on the sensory bristle, thus conferring female nonreceptive behavior.

1.5.3.7.1. Caste-dependent plasticity In the honeybee, *A. mellifera*, secretions of female's Dufours gland differ in composition between the queen and her cohort worker bees (Katzav-Gozansky *et al.*, 1997). A fertile queen's Dufours gland produces a blend of esters (queen pheromone) that control worker bee behavior (Katzav-Gozansky *et al.*, 2003; see **Chapter 3.13**). In a colony with a fertile queen, worker bees do not produce these esters; instead they produce the corresponding alcohols, although their Dufours glands can be stimulated to produce esters when incubated *in vitro* (Katzav-Gozansky *et al.*, 2000). However, if a queen is removed from a colony, stimulating ovary maturation in workers, the workers' Dufours glands now begin to produce esters *in vivo*. Thus, it appears that a gonadal gland of fertile queens produces esters that regulate the caste and ester production by workers in her colony. In the queen's physical or functional absence, workers can co-opt her social status and her gonadal glands' ability to produce these esters.

1.5.3.7.2. Transgenerational behavioral modification Locusts can exhibit a continuum of types of behaviors, ranging from being extremely solitary to being extremely gregarious. The accessory glands of ovipositing locust females produce a factor that affects the subsequent behavior of her offspring. This factor is a part of the froth enveloping the egg pod and composing the foam plug above the deposited egg batch. Ligation of the distal accessory glands of crowded females demonstrated that in the absence of the glandular material, the locust nymph behavior significantly shifted towards solitary behavior, compared to conspecific nymphs from control-treated females (Hägele *et al.*, 2000). The intensity of the phase characteristics of locusts is due not only to the population density of the current generation, but is intensified by the phase history of previous generations (see Uvarov, 1966). Depending on parental population density, isolated larvae are more typically solitary in morphometrics, coloration, and behavior and, conversely, crowded larvae are more typically gregarious. Enhanced cumulative (trans-generational) gregarious characteristics are attributed to a small (<3 kDa), hydrophilic labile "gregarizing" factor which is produced at the time of egg deposition and which predisposes neonate nymphs to attain characteristics of the gregarious phase (McCaffery and Simpson, 1998). The presence of three ketones: (*Z*)-6-octen-2-one, (*E*,*E*)-3,5-octadien-2-one, and (*E*,*Z*)-3,5-octadien-2-one – in the foam and in gregarious female accessory glands – has been reported (Malual *et al.*, 2001). They may be part of the repertoire of maternal effects resulting in gregarious locusts, but this requires further study.

1.5.3.8. Supporting Larval Development

In viviparous species of some Diptera, progeny larvae develop within the uterus of the female. Products of the female's accessory glands, called "milk glands" in these species, enhance female fertility by supporting the development of these larvae, apparently by furnishing the larvae with nutrients or other components needed for development. For example, in the tsetse flies *Glossina morsitans morsitans*, pregnant females develop an extensive tubular network of milk glands to mediate the transfer of nutrients to larvae developing within their uterus (Yan *et al.*, 2002). Chitinase (see **Chapter 4.3**) is among the proteins produced by these milk glands and can be detected in intrauterine larvae and pupae, although no mRNA for chitinase can be detected in these intrauterine larvae (Yan *et al.*, 2002), suggesting that they obtained their chitinase from their mother's milk glands. A major protein of the mother's milk glands is synthesized as her larvae molt to the second instar and protein levels decline rapidly as the larva matures. Osir *et al.* (1991) hypothesized that this protein could provide essential amino acids needed for the larva to form a puparium. Finally, Cmelik *et al.* (1969) found that the midgut of developing larvae also contained proteins, peptides, and free amino acids and lipids

(phospholipids, cholesterol, and triglycerides) derived from the mother's milk glands. It was not clear whether the lipids had been made in the milk glands or were derived from the fat body and later sequestered in the milk glands (see also Gillott, 1988).

1.5.3.9. Anti-Immune Molecules

Eggs deposited by parasitic wasps within lepidopteran larvae are accompanied by molecules and macromolecular complexes that co-opt the host's physiology to allow development of the parasitoid. Female gonadal glands of the parasitoid are the source of some of the host-modifiers that are injected into the host along with the parasitoid's eggs.

For example, secretions from the oviduct of the scelionid egg parasitoid *Telenomus heliothidi* appear to regulate, and halt, host development (Strand *et al*., 1980), perhaps by stimulating production of a family of growth blocking peptides (GBP) that possess diverse biological activities associated with immunological defense mechanisms and response to stress (Aizawa *et al*., 2001). Finally, Chelonine wasps usurp development and reproductive control of their immunologically compromised lepidopteran hosts by down-regulating host JH production, thereby inducing precocious metamorphosis and preventing reproductive maturation. These responses may be due to a variety of effectors introduced into the host larvae during deposition of the endoparasite egg that are reinforced subsequently by the parasitoid larva (Jones, 1996). For example, polydnaviruses (e.g., from *Cotesia congregata*) interfere with the host larval immune response against the deposited egg (see **Chapter 6.10**). These viruses replicate in the adult parasitoid's ovarian calyx cells (Savary *et al*., 1999). Their bioactivity is attributed to specific immunoevasive proteins (IEPs) in the virion surface coat. IEPs, which are encoded in the parasitoids genome, and are transcribed, translated, and secreted in the lateral oviduct (Tanaka *et al*., 2002). Thus, the parasite has evolved to take advantage of the synthetic capacity of gonadal glands and the ability of gonadal gland secretions to accompany the egg. Another ichneumonid endoparasitoid, *Venturia canescens*, inhibits permissive host hemolymph defense melanization against the parasitoid egg, by injecting a serpin from the ovarian calyx fluid (Beck *et al*., 2000).

1.5.4. Male/Female Interactions and Evolutionary Considerations

1.5.4.1. Male–Female Interactions at the Cellular and Molecular Level

Apart from whole-organism interaction between male and female insects, reproduction involves interaction between male- and female-derived molecules and cells. Perhaps the best known of these are the interactions between sperm and oocyte, which result in fertilization (see **Chapter 1.6**). Although in many organisms this interaction also activates the oocyte to support embryo development, in at least some insects sperm penetration is not necessary to activate oocytes, e.g., in *Pimpla turionellae* (Went and Krause, 1974) and other haplodiploid hymenopterans whose unfertilized eggs develop into males as well as in *D. melanogaster* (Doane, 1960; Mahowald *et al*., 1983; Page and Orr-Weaver, 1997; Heifetz *et al*., 2001b). Male–female cellular and molecular interactions include also those between female reproductive tract cells or molecules, and male-derived molecules or sperm cells. These interactions, many of which were discussed in previous sections of the chapter, modulate sperm storage, maintenance, and utilization, and regulate female reproductive physiology and behavior.

A final area of interaction is one that the authors hypothesize – a give-and-take between male and female that results in "priming" the female's reproductive tract for efficient fertility. It is suggested that efficient fertilization requires an oviduct environment, or "ecology," that best supports the final maturation of the egg and the sperm and promotes their union. In mammals, the female reproductive tract undergoes hormonally mediated cyclic modifications in morphology and secretion, resulting in an optimal environment for gametes and fertilization during the preovulatory period (e.g., Salamonsen *et al*., 1994). It is proposed that an analogous change might occur in insects, though in this case the hormonal triggers could be mating, sperm, or gonadal gene products from the male. This model is based on experiments in *Drosophila*. Virgin female *Drosophila* make, ovulate, and deposit eggs at a low rate; receipt of gonadal gland secretions from their mates stimulates the rate of these processes. Heifetz and Wolfner (2004) have shown that mating, and in some cases male accessory gland secretions, modulate the release of vesicle contents from peptidergic nerve termini innervating parts of the female reproductive tract. That these vesicles were ready for release before mating indicates that the female was physiologically "poised," and awaiting only mating signals to progress into an advanced reproductive state. Thus, it is proposed that mating, sperm, and male gonadal secretions trigger a final maturation of the female's reproductive capacity, switching her from a "virgin" physiological state to a "mated" physiological state (**Figure 2**). In *Drosophila*, such a sensitizing event presumably can occur in any mating, but for insects such as those moths that

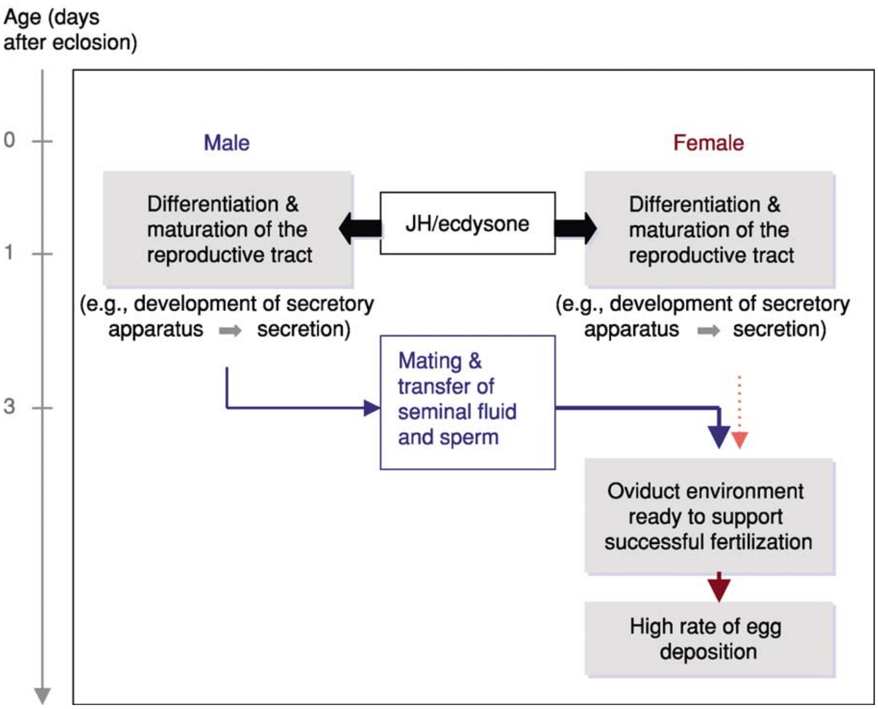

Figure 2 Model for conversion of female reproductive tract from virgin to mated state by male-donated effectors. See text for details.

mate only once in their lifetime, this sensitization only occurs once and its effects would then be "fixed" cellularly and/or molecularly.

1.5.4.2. Evolutionary Considerations

That male gonadal products trigger post-mating changes in the female would seem, on first consideration, to be advantageous to both the male and the female. For example, it would seem to be in both the female's and the male's interests to tie increased egg production to mating: the female would thus allocate resources to egg production only when sperm are present to fertilize her eggs, and the male would have more progeny, more rapidly. Although the male provides physiological modifiers that can modulate the female's reproductive capacity, the female is not a passive player in the reproductive interaction. Eberhard (1996) recounts many examples in which the female exerts control over the reproductive fate of her mate's gametes. In an example consistent with the *D. melanogaster* female genotype, the female influences the outcome of sperm competition (Clark and Begun, 1998). One could imagine that through natural selection, females have evolved strategies to "exploit" the male as a source of timed critical regulators of female physiology. For example, having the male provide the molecules that up-regulate egg production provides a fail-safe switch to couple changes in resource allocation to mating.

Yet, all may not be as cooperative as implied by part of the previous paragraph. Several experiments and theories posit that the interactions between males and females also have the potential to reflect opposing interests (e.g., Rice, 1996; Holland and Rice, 1999; Rice and Chippindale, 2001; review: Chapman *et al*., 2003a). For example, it may be to the male's advantage to induce his mate to produce more eggs after mating than her long-term well-being can tolerate. This could drive the evolution of female-resistance to the male inducers of increased egg-production, keeping the effects to tolerable levels for females. This might in turn select for males who can make more potent inducers, driving additional changes in the inducing molecules, whereas, theoretically, strict monogamy, whether by choice or enforced experimentally, should lead to evolutionary harmony of sexual interaction. Deviation from this state could increase the potential for conflict between the interests of the male and of the female, that could reinforce inter-sexual antagonistic coevolution (Hosken *et al*., 2001). Another potential example of conflicts between males and females is the "cost-of-mating," discussed in a separate section below. Finally there can be other pressures driving the evolution of molecules in reproductive tracts, such as co-evolution of protective molecules with pathogen types that are introduced during mating.

An unusually high proportion of *Drosophila* male accessory gland proteins and the genes that encode them show evolutionary dynamics that are consistent with these models (Coulthart and Singh, 1988; Aguadé *et al*., 1992; Cirera and Aguadé, 1997, 1998a, 1998b; Tsaur and Wu, 1997; Aguadé, 1998, 1999; Tsaur *et al*., 1998, 2001; Ravi Ram and Ramesh, 1999, 2001; Begun *et al*., 2000; Swanson *et al*., 2001). For example *Drm*-Acp26Aa, the ovulation hormone described previously, is the most rapidly-evolving gene identified to date in *Drosophila* (Tsaur and Wu, 1997; Aguadé, 1998; Tsaur *et al*., 1998, 2001). In another example, the percent of predicted *Drosophila* male accessory gland proteins that show elevated rates of nonsynonymous amino acid substitutions is ten-fold higher than for control, nonreproductive genes (Swanson *et al*., 2001). Evolutionary modulation also has occurred in terms of the expression of the enzyme glucose dehydrogenase. This enzyme is expressed in the ejaculatory ducts of some *Drosophila* species but not others, and its expression there correlates with the morphology of the ejaculatory duct (Cavener, 1985).

One outcome of sexual conflict can be redundancy or degeneracy, the latter being the presence of totally different molecules serving the same function (Edelman and Gally, 2001). As males evolve multiple effectors to compensate for those to which females have become resistant, redundancy and degeneracy can also shield essential female processes from complete cessation if one of their male effectors changes so much that its effectiveness is lost. Because of redundant or degenerate effectors, loss of one effector of an essential reproductive processes could decrease fertility levels but not cause sterility. This is in fact what is observed in *D. melanogaster*: all knockouts/knockdowns of specific male accessory gland proteins retained some residual fertility (Herndon and Wolfner, 1995; Neubaum and Wolfner, 1999a; Heifetz *et al*., 2000; Chapman *et al*., 2003b; Liu and Kubli, 2003). That this is likely due to redundant/degenerate effectors is perhaps best illustrated for the sex peptide *Drm*-SP. Females mated to males that lack this molecule still increase their egg production a bit after mating (Chapman *et al*., 2003b; Liu and Kubli, 2003). This likely reflects the continued availability of *Drm*-Dup99B (Saudan *et al*., 2002) and Acp26Aa (Herndon and Wolfner, 1995; Heifetz *et al*., 2000), as well as potentially of other modulators of the egg production process in the seminal fluid of SP-deficient males. Another way to shield complex multi-step processes from cessation, if their sole male-provided regulator became too divergent to function, is to have them regulated by multiple effectors that act at separate steps. This could also allow "fine-tuning" at several levels to allow the process to be at optimal efficiency (Heifetz *et al*., 2000; Bloch Qazi *et al*., 2003). In mated female *D. melanogaster*, several reproductive processes are indeed regulated at different steps by male gonadal gland products. For example, SP stimulates oogenesis (Soller *et al*., 1997, 1999) whereas Acp26Aa increases ovulation rate (Heifetz *et al*., 2000; Chapman *et al*., 2001). Thus, these two molecules could act synergistically to increase egg-production.

The picture may be still more complicated than this, however, because in species that mate multiple times there can be competition among males. For example, in *Drosophila* females that mate more than once, sperm from the first mating can be competed, or displaced, by sperm from a subsequent mating. Females can play a role in this, by choosing sperm from a preferred mate (i.e., sperm preference; Eberhard, 1996; Clark and Begun, 1998), but there also appears to be a role for male gonadal secretions in the competition between sperm of different males (Harshman and Prout, 1994; Clark *et al*., 1995; Price, 1997; Chapman *et al*., 2000). Thus, the possibility exists for evolutionary pressures to drive changes in seminal proteins that mediate male–male interactions within the females with which they had mated.

1.5.4.2.1. Cost-of-Mating Mating of animals can impose a cost on their longevity. In some cases, the longevity of both sexes is decreased because there are trade-offs in resource allocation between up-regulated reproductive functions and, for example, immunity, and these trade-offs can reduce the overall fitness of a mated animal (Rolff and Siva-Jothy, 2002). But of particular relevance to the topic of this article is the observation that mated female *D. melanogaster* and *C. capitata* die sooner than equivalent females who have not mated (Partridge *et al*., 1987; Fowler and Partridge, 1989; Partridge and Fowler, 1990; Chapman *et al*., 1995, 1998). While some cost is extracted on *D. melanogaster* females simply by exposure to males, perhaps reflecting behavior-related "costs" analogous to those that shorten the lives of mated male insects (e.g., *Drosophila* (Cordts and Partridge, 1996); versus "horned" and "unhorned" dung beetles *Onthophagus binodis* (Kotiaho and Simmons, 2003)), two components of the cost-of-mating to female *D. melanogaster*, relate to processes linked directly or indirectly to seminal proteins.

The first is that mating results in increased egg production as noted above, due in part to transfer of male gonadal products that stimulate

egg production in females. This expenditure depresses the lifespan of the mated female: energy expended to make eggs cannot also be used to sustain life. In the Mediterranean fruit fly, *C. capitata* and in the adzuki bean beetle, *Callosobruchus chinensis*, mating and egg production are also seen to impose independent costs (Chapman *et al.*, 1998; Yanagi and Miyatake, 2003).

The second effect of male-derived proteins on female longevity is seen, when experiments are conducted so as to remove the contribution of egg production to longevity (Chapman *et al.*, 1995). In this case, a significant effect of products of the male's accessory gland is seen to modulate the longevity of mated females. Whether males have evolved to extract a cost-of-mating from their mates (Johnstone and Keller, 2000), thus potentially limiting their mates' potential for future matings with competitor males, or whether the cost-of-mating is an unintended consequence of a deleterious by-product of an essential reproductive activity provided by males (Lung *et al.*, 2002), is an open and pressing question.

The molecular identity of the gonadal gland products that contribute to the cost of mating is as yet unknown. In *D. melanogaster*, genetic or RNAi experiments indicate that the ovulation hormone *Drm*-Acp26Aa, and the sperm storage protein *Drm*-Acp36DE do not contribute to this effect (Neubaum and Wolfner, 1999a; Chapman *et al.*, 2000, 2001). A candidate contributor to the cost of mating in this insect is the trypsin inhibitor Acp62F. This protein, derived from the male's accessory glands, enters the circulation of the mated female. It is toxic to flies, upon ectopic expression (Lung *et al.*, 2002). Perhaps after entry into the female's circulation Acp62F inhibits essential proteolytic cascades, causing a deleterious effect on the female. However, whether its toxicity is in fact the cause of the cost of mating remains to be demonstrated.

1.5.5. Future Perspectives and Practical Considerations

The analysis of insect reproduction in general, and of gonadal glands and their products in particular, is of broad significance in basic biology – not simply reproductive biology – and has practical applications. The vast diversity in the structures and functions of gonadal glands, and in the ways that different insects exploit these to their own ends, provides windows into the control and plasticity of physiology and behavior. That gonadal gland products from the male cause physiological changes in their mates provides tractable entry points (and zero-time-points) from which to study and modulate hormonal processes in the female reproductive tract, an advantage over studying physiology in a steady state. In another example, the fact that some gonadal gene products mediate cell targeting (e.g., sperm migration into storage), cell interaction (e.g., egg movement down the reproductive tract) and other basic processes, means that their elucidation may provide generally-applicable paradigms.

Studies of insect reproductive strategies and the molecular interactions that modulate them may provide information for evaluation of evolutionary models, and for the study of metabolic and regulatory pathways. For example, perhaps there are conserved pathways that regulate physiological events in female insects – but their proximal triggers have evolved to become divergent. Conversely, despite diversity in mating strategies and in pre- or post-mating behavior, some gonadal gene products cross-react across a range of insects (e.g., *Drm*-SP in *D. melanogaster* and *H. armigera*). In these cases, homologous bioactive peptides and proteins may act to similar ends and even by similar means, but within the context of markedly differing reproductive strategies of the different insect species. For example, although tephritid females show changes in sensory behavior post-mating, such as orienting to fruit for egg deposition rather than to leks for mate-choice, whereas noctuid moths show a cessation of pheromone production after mating, suggesting a change in pheromone biosynthetic pathways, it is possible that homologous effectors from their mates' gonadal glands could trigger the changes that led to these responses. Moreover, the outcomes are similar: in both cases, the net result is that priorities are affected and subsequent mating is deferred. Finally, as noted earlier, a significant number of *Drosophila* gonadal gene products show signs of having been subject to positive selection. Indeed, some are therefore a rich source of novel protein sequences and structures, and experiments to determine their function will assist in understanding these dynamics. As more genomic sequences are determined and analytic methodologies improve, it will be interesting to test the generality of this conclusion. There is evidence already for the rapid evolution of reproductive proteins in a number of systems (Swanson and Vacquier, 2003).

For insects in which the molecules produced by gonadal glands are known, or in the process of becoming known, the challenge and excitement will be to identify their specific functions and how those are carried out. In other insects, the functions of gonadal glands and their products are a mystery awaiting elucidation. In either case, ultimately, the

identification of the functions of insect gonadal glands will be important for practical reasons as well as their intrinsic interest. Insects are extremely prolific, and they include species that are very important agricultural helpers (e.g., honeybees) or pests (e.g., locusts or armyworms) and also play important roles as vectors of several devastating human diseases (e.g., some mosquitoes). Thus, under some circumstances, it can be important to find ecologically-rational, nonchemical methods of controlling the reproduction of particular insects. With the important role that gonadal glands and their products play in insect reproduction, it seems likely that they will be among the most important areas of investigation to exploit in order to attain their use in biological control.

Acknowledgments

We thank M. Bloch Qazi, Y. Gottlieb, H. Hagedorn, J. Mueller, K. Ravi Ram, and A. Wong for helpful suggestions. We appreciate support from NIH (grant HD38921 to MFW) and BARD (grant IS-3492-03 to YH), as well as ISF (grant 486/01-17 to SWA) and the Israel Ministry of Agriculture (grant 824-0100-03 to YH and SWA).

The authors wish to dedicate this chapter to the memory of Dr David Applebaum and Ms. Nava Applebaum.

1.6 Molecular Genetics of Insect Fertilization

B Loppin and T L Karr, University of Bath, Bath, UK

1.6.1. Insect Fertilization – A Brief Overview

There is no doubt that fertilization is a central and key event in the life histories of all sexually reproducing organisms. It is also equally clear that we have little understanding of the evolution of sex or its maintenance throughout the over 600 million years of its existence. The selective forces that led to the origin of sex are shrouded in mystery and complexity, and indeed many consider sex to be, "…the Queen of problems in evolutionary biology" (Bell, 1982). The evolution of sex and related issues continues to dominate current evolutionary thought (Bell, 1982; Hamilton, 1999; Ridley, 1994; West-Eberhard, 2003). There exists a strange duality in our study and intellectualization of this topic: sex is a universal trait founded deep in evolutionary history while at the same time one of the most variable. This paradoxical duality challenges our ability to study, and indeed even to know how to study, those aspects of sex that can shed light on these important questions. Therefore, it is to be expected that deeper understanding of fertilization at the cellular, molecular, and genetic levels will not only provide much needed information about the process *per se*, but should also help to shed light on the much bigger issues fundamental to the evolution of sex noted above.

Fertilization has been studied in both mammalian and marine invertebrates for decades and the vast majority of information has come from these systems (Vacquier *et al.*, 1997; Sutovsky and Schatten, 1998; Vacquier, 1998; Jonakova *et al.*, 2000; Mori *et al.*, 2000; Swanson *et al.*, 2001, 2003; Galindo *et al.*, 2003; Payne *et al.*, 2003). We now know much about some of the molecules involved in egg activation, sperm capacitation, sperm-egg recognition, and membrane fusion. Although these can all be considered "universal" aspects of fertilization, there is a bewildering array of variations on these themes, which presumably reflect the unique selective constraints and evolutionary history of the individual lineages under study. Perhaps one of the most important results to come from these studies is the demonstration that some of the molecules known to be directly involved in the fertilization process are under strong directional (positive) selection, suggesting an important role in speciation (Vacquier, 1998; Swanson and Vacquier, 2002). Unfortunately, these systems are limited in part because they lack the genetics needed to validate and extend deeper into the pathways involved. In this regard *Drosophila* should be the ideal model system for both genetic and molecular studies of fertilization, although progress in this area has been overshadowed by other advances, for example axial

patterning (see **Chapters 1.2** and **1.8**) and gene regulation, for which *Drosophila* is so well known.

The number of reviews written on the subject of insect fertilization over the recent past is relatively small compared to its mammalian and noninsect invertebrate counterparts. For example, according to a cursory web-based literature search over the past 10 years, there have appeared no fewer than 25 reviews focused on mammalian and non-insect invertebrate groups compared to just four for insects. There are many reasons for this discrepancy. Most are practical in nature, as mammalian and echinoderm systems are easily studied in the laboratory and we, therefore, know correspondingly more about fertilization in these groups. Also, insects are generally, when it comes to fertilization, much more secretive about their sexual activities. Fertilization is often internal and well hidden from prying eyes (the opaque and tough chitinous exoskeleton (see **Chapter 4.4**) being one example of the obstacles thrown up), and *in vitro* fertilization systems have not yet been developed. Thus, biologists interested in insect fertilization have historically focused on cytological descriptions of fixed embryos during early events following sperm entrance (Sander, 1985; Karr, 1996; Fitch *et al*., 1998).

Fortunately, this is now changing through genetic studies that have either directly or indirectly identified genes involved in various aspects of *Drosophila* fertilization. In this chapter, we describe these studies and, where applicable, compare and contrast them to the mammalian and noninsect systems. As mutants that disrupt or abolish crucial key steps in the fertilization process are further identified and characterized, *Drosophila* will continue to become a more useful tool for the study of this important developmental process. For example, both maternal- and paternal-effect lethal mutations have been identified and provided key new insights into the early events of fertilization, while at the same time providing future directions for research.

Interestingly, one of the driving forces for renewed interest in *Drosophila* fertilization comes from studies of *Wolbachia*, an intracellular microbe that lives in insect gonadal tissues and can disrupt the fertilization process. This intriguing microbe infects an astonishing diversity of arthropods and crustaceans and, in doing so, causes an equally astonishing effect on host reproductive biology (Stouthamer *et al*., 1999). These effects are often targeted in the male, and of particular interest to fertilization biologists, *Wolbachia*-infected animals express a form of fertilization failure termed cytoplasmic incompatability (CI) that results in developmental defects following sperm entrance. Further work on the cellular basis of CI should provide insights into basic mechanisms of fertilization.

Finally, as a chapter focused on the molecular genetics of fertilization, this review will necessarily be limited to *D. melanogaster*, and hopefully will be illustrative of this group of dipterans. However, we understand dipterans make up only a small fraction of the Insecta and, therefore, realize that although this review represents a comprehensive review of molecular genetics in *D. melanogaster*, it should not be taken as representative of Insecta in general. Having said that, the final sections deal with fertilization in other insects, where new information relevant to specific problems in fertilization biology has come to light in recent years.

1.6.2. Some Aspects of Fertilization in *Drosophila* are Fundamentally Different from Mammalian and Echinoderm Systems

It is a curious happenstance of scientific history that fertilization was first studied extensively in marine invertebrates such as the now famous purple sea urchin (*Stronglocentrotus purpuratus*). This was the organism of choice for developmental biologists because of the easy access to both gamete types and the ability to perform large-scale *in vitro* fertilization experiments. These pioneering studies led to our current view of fertilization (e.g., see Gilbert, 1988). However, there are three ways, in which fertilization differs between these groups and insects: (1) syngamy, defined as the fusion between gamete plasma membranes, does not occur. This remarkable finding was clearly demonstrated by Perotti almost 30 years ago (Perotti, 1975). It is entirely unclear how this seemingly crude method of entry is initiated, facilitated, or regulated. It is also unclear how the sperm membranes are broken down following entrance; and (2) insects undergo a gonomeric division that has been well-described in a number of insect groups. Gonomeric division is characterized by a delay in fusion of the parental chromosomes; instead, they remain separate during the first mitotic division, and parental chromosome sets fuse only after telophase; and (3) unlike most other taxa, insects in general, and *Drosophila* in particular, make much longer sperm (Pitnick and Markow, 1994; Pitnick *et al*., 1995; see also **Chapter 1.4**). Sperm gigantism is a conundrum of developmental biology with as yet no answer, although some hypotheses have been put forward (Karr, 1991, 1996; Karr and Pitnick, 1996; Pitnick and Karr, 1998).

What is clear is that for many species, including many mammalian, avian, and marine invertebrates, total sperm entrance is a common occurrence. This fact has been known for some time but either under-appreciated or ignored. Thus, a total understanding of fertilization must include the process of sperm entry into the egg, including the sperm flagellum and paternal mitochondria (or its derivative). The fate of these giant structures in the egg has some important implications for sexual organisms (Pitnick and Karr, 1998) but is beyond the scope of this review.

1.6.3. Essential Features of *Drosophila* Fertilization

As a key step of developmental biology, fertilization has surprisingly received very little attention from geneticists until recently. This is now changing in part, because this very first step in development is also providing crucial clues for the understanding of many essential aspects of modern biology, such as epigenetics, chromatin assembly/remodeling, and cell cycle regulation. For example, extensive genetic screens in the nematode *Caenorhabditis elegans* have identified genes essential for the formation of the zygote (Ward and Miwa, 1978; Achanzar and Ward, 1997; Royal *et al*., 1997; Bowerman, 1998; Singson *et al*., 1998; Miller *et al*., 2001; Singson, 2001; Xu and Sternberg, 2003). Interesting advances have also been achieved in mammals, with the first few mutants affecting zygote formation identified in mice (Christians *et al*., 2000; Tong *et al*., 2000; Wu *et al*., 2003a, 2003b). It will, therefore, be of great interest to insect developmental biologists to compare and contrast these findings with similar ongoing work in *Drosophila*. In the following sections of this chapter, we will review basic processes associated with fertilization, and present recent advances in the molecular genetics of fertilization in *Drosophila*.

The large majority of drosophiliids studied are strict bisexually-reproducing species, which means that fertilization of the egg is absolutely required for embryonic development to occur. However, this is not always the case in the genus *Drosophila*. Several species can partially reproduce by parthenogenesis, and at least one species (*D. mangabeirai*) has been described to strictly reproduce parthenogenetically (Murdy, 1959).

1.6.3.1. Cytological Aspects of *Drosophila* Fertilization and Zygote Formation

In *D. melanogaster*, fertilization occurs in the uterus, shortly after egg ovulation. A relatively small number of sperm are stored in two different organs in the female genital tract, the sperm receptacle and the spermathecae (see **Chapter 1.5**). Eggs are usually deposited shortly after fertilization but embryonic development can also begin before egg deposition. The formation of the diploid zygote occurs very rapidly in this species, and it takes only about 17 min from sperm entry to the end of the first zygotic division. In comparison, the same event lasts about an hour in the wasp *Nasonia vitripennis* (Tram and Sullivan, 2002). The following syncytial nuclear divisions of the early *Drosophila* embryo are among the fastest mitoses described in metazoa, the first cycles lasting less than 10 min.

The cytological events that take place in the egg at fertilization have been described with great accuracy by Sonnenblick (Sonnenblick, 1950) and are presented in diagramatic form in **Figure 1**. The mature *Drosophila* oocyte is arrested in metaphase of the first meiotic division (**Figure 1a**, sperm entrance). The metaphase I spindle is located near the egg surface, in an antero-dorsal region. Ovulation is the signal for female meiosis to resume and is concomitant with sperm entry. The second meiotic division is easily recognized by the presence of two anastral spindles associated in tandem, orthogonally to the surface of the egg (**Figure 1b**). In insects, the four meiotic products remain in the egg: the innermost nucleus is determined to become the female pronucleus whereas the three other nuclei form the polar bodies. The polar bodies eventually fuse into a triploid nucleus that remains blocked in a pseudo-metaphase state at the egg periphery and that does not participate in the development of the embryo (star-like structures in **Figure 1e–h**). The mature sperm nucleus in *D. melanogaster* is a highly elongated, 9 μm long, needle-like structure that contains extremely compacted paternal chromatin that must rapidly decondense in the egg cytoplasm to form the male pronucleus.

During the second meiotic division, the sperm nucleus already appears as a round, yet still condensed, nucleus that migrates towards a more centrally located zone of the egg (**Figure 1b**). During and after migration, the sperm pronucleus decondenses its chromatin and reassembles a nuclear envelope from egg components. A pair of centrioles that is located at the base of the flagellum in the basal body is delivered in the egg cytoplasm after the sperm cell membrane breakdown (**Figure 1c**). This is a crucial component because it contributes the first centrosome of the diploid embryo. A large aster, called the sperm aster, develops from the sperm-derived MicroTubule Organizing Center (MTOC) and radiates to the egg periphery (**Figure 1c**). During

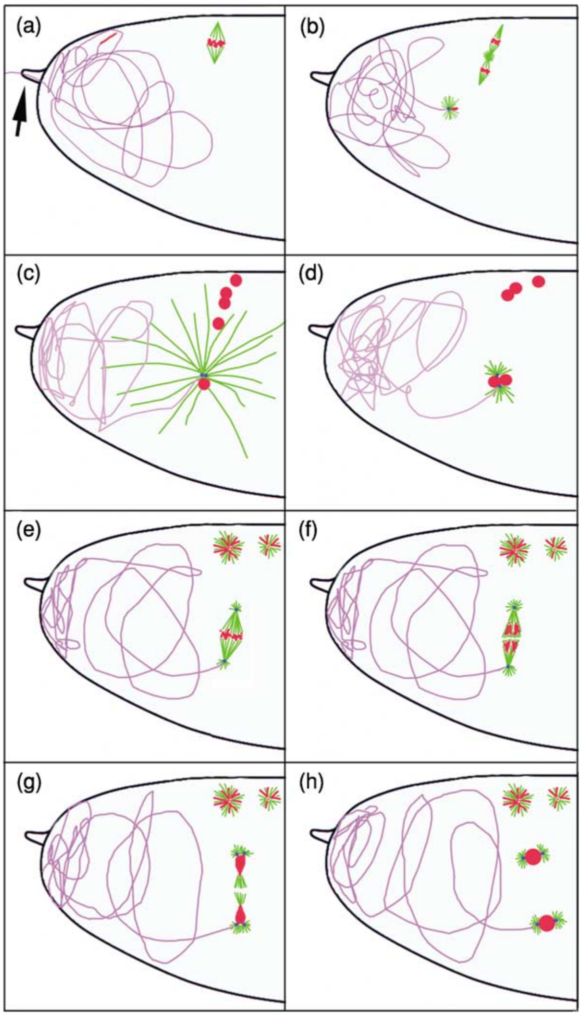

Figure 1 Fertilization in *Drosophila*. (a) Sperm entry. The spermatozoon enters the egg through the micropyle and its flagellum coils in the anterior part of the egg cytoplasm. The sperm nucleus is still very condensed at this stage. The anastral female meiotic spindle is close to the antero-dorsal periphery of the egg. Female meiosis is arrested in metaphase of the first division until egg activation, which is concomitant with sperm entry. (b) Meiosis II. The two meiotic spindles are organized in tandem around a central aster, orthogonally to the egg surface. The sperm nucleus has migrated towards a more central position. A new nuclear envelope has formed around its chromatin that has begun to decondense. A centrosome has formed around the pair of centrioles that are derived from the sperm basal body. (c) Pronuclear formation. Female meiosis produces four haploid nuclei that remain in the egg cytoplasm. The innermost nucleus is determined to become the female pronucleus whereas the three other nuclei remain at the periphery to form the polar bodies. The sperm centrosome duplicates to form the MTOC at the origin of the sperm aster. (d) The female pronucleus migrates towards the male pronucleus, along the microtubules of the giant sperm aster. At the end of its migration, the female pronucleus apposes to the fully decondensed male pronucleus. Pronuclear fusion does not occur at this stage. The sperm aster is progressively replaced by two MTOC that organize the first mitotic spindle. (e) Metaphase of the first zygotic division. Each set of parental chromosomes occupies one half of the gonomeric spindle. The sperm tail remains associated with one of the sperm-derived centrosomes. Chromosomes of the polar bodies have also recondensed into star-like configurations. Usually, the two central meiotic products fuse into a diploid polar body. Frequently, a single triploid polar body is eventually observed at the egg periphery in older embryos. (f) Anaphase. Paternally-derived and maternally-derived sister chromatids remain separated during their migration to the spindle poles. (g) Telophase. Parental genomes fuse only at the end of telophase. Centrosomes duplicate at this stage to prepare next mitosis. (h) Interphase of the second nuclear cycle. Each diploid nucleus is associated with a pair of centrosomes. The sperm tail remains attached to one of them.

its migration, the female pronucleus uses the microtubules from the sperm aster to migrate inwards to its male counterpart. Both pronuclei are eventually found apposed in a central position of the egg. It is important to note that the pronuclei do not fuse in insects (at least in those species where this process has been documented). Instead, they replicate their DNA and proceed into a gonomeric division (metaphase, Figure 1e), where both parental sets of chromosomes divide independently within a

common spindle (anaphase, **Figure 1f**). Each set of chromosomes occupies one half of the gonomeric spindle until telophase (**Figure 1g**) when parental genomes eventually fuse to form the first two diploid nuclei (**Figure 1h**). The gonomeric division is a crucial advantage for the analysis of fertilization mutant phenotypes, because it allows one to distinguish mutants that affect one set of parental chromosomes without affecting the division of the other (see below).

During the time used for female meiosis to resume, a single spermatozoon enters the egg through the micropyle and delivers its nucleus into the egg cytoplasm. Polyspermy, the entrance of more than one sperm, has been observed rarely in *D. melanogaster* (<1%) with higher rates observed in some crosses of *D. pseudoobscura* (Snook and Karr, 1998). Polyspermy in these cases results in participation of only a single male pronucleus in zygote formation.

Drosophila spermatozoa are characterized by a gigantic flagellum that can reach the amazing size of several centimetres in some species (Joly *et al*., 1995; Pitnick *et al*., 1995). A survey of the genus revealed tremendous variation in sperm length over the entire spectrum of species within this clade (Pitnick, 1996). For example, *D. melanogaster* sperm are about the size of the adult male (~1.8 mm), while sperm in members of the *virilis* subgroup, e.g., *D. virilis, D. montana, D. littoralis*, are considerably longer and many times their body length (5–8 mm) (see also **Chapter 1.4**). Incredibly, in almost all cases observed, the entire male gamete completely enters the egg cytoplasm. This rather fantastic observation was first seen in sectioned eggs (Hildreth and Lucchesi, 1963) and was later described in whole-mount eggs using sperm-specific antibodies (Karr, 1991), and later shown (Karr and Pitnick, 1996) to be a regular phenomenon in numerous species (**Figure 2**). To achieve this tour de force, the flagellum is coiled into several loops in the anterior part of the egg. During early development, the sperm flagellum remains in the anterior part of the embryo and is partially degraded. What remains of this structure is eventually internalized in the embryonic gut before being eliminated with the larval wastes (Pitnick and Karr, 1998).

What is the purpose of such extraordinary long sperm? This question, first raised over a decade ago (Karr, 1991), has as yet no clear answer. One possibility is that the "sperm-derived structure" has some as yet unrecognized postfertilization function. However, studies of the patterns of sperm tail entrance during fertilization in *D. hydei* and *D. bifurca* (where only a small fraction of the sperm enters the egg), clearly demonstrated that the complete sperm entrance is not an absolute requirement for fertilization (Karr and Pitnick, 1996). Indeed, comparative phylogenetic analysis of the patterns of fertilization in these groups demonstrated that over 35 mm of sperm length evolution occurred in the male that did involve a postfertilization function (Karr and Pitnick, 1996). The fact still remains, though, that several millimeters of sperm flagellum enter the egg upon fertilization in all cases studied, and the function, if any, of the resulting sperm-derived structure has not been resolved.

While direct postfertilization functional studies of sperm have yet to be conducted, some clues about the evolutionary significance of sperm-female co-evolution have recently emerged from laboratory selection studies. These studies selected on both female receptacle and sperm length in *D. melanogaster* and resulted in two clear classes of populations which differed significantly (Miller and Pitnick, 2002). Miller and Pitnick went on to show that females could discriminate between sperm in competition experiments, showing convincingly a role for sperm length in reproductive fitness. However, the ability of the female to discriminate among sperm of differing lengths does not directly answer the question as to why the entire structure enters the egg. Future functional studies are needed to provide a more complete overall picture of sperm utilization by females, the evolution of sperm gigantism and fertilization. As described further below, a genetics approach has proven extremely successful in identifying genes involved in early stages of fertilization.

1.6.3.1.1. Sperm heteromorphism in *Drosophila* – an evolutionary enigma It is a common occurrence for some groups of insects to produce more than one class of sperm. Termed polymegaly, or sperm heteromorphism, this phenomenon has best been described in the Lepidoptera where there is production of two distinct sperm types, a eupyrene type that contains a haploid genome and an apyrene type that contains no DNA but otherwise is normal. Apyrene are often motile and can be produced in large quantities. The significance and function of apyrene sperm is not known (see Section 1.6.6.4.2 for further discussion of lepidopterans).

Although rare in *Drosophila*, the *obscura* subgroup is distinguished by the presence of two sperm classes, short and long (review: Snook, 1997). Unlike lepidopterans, *Drosophila* of both short and long sperm types in this group produce DNA-containing sperm and therefore both should be fertilization competent. However, it has been shown quite convincingly that only the longer

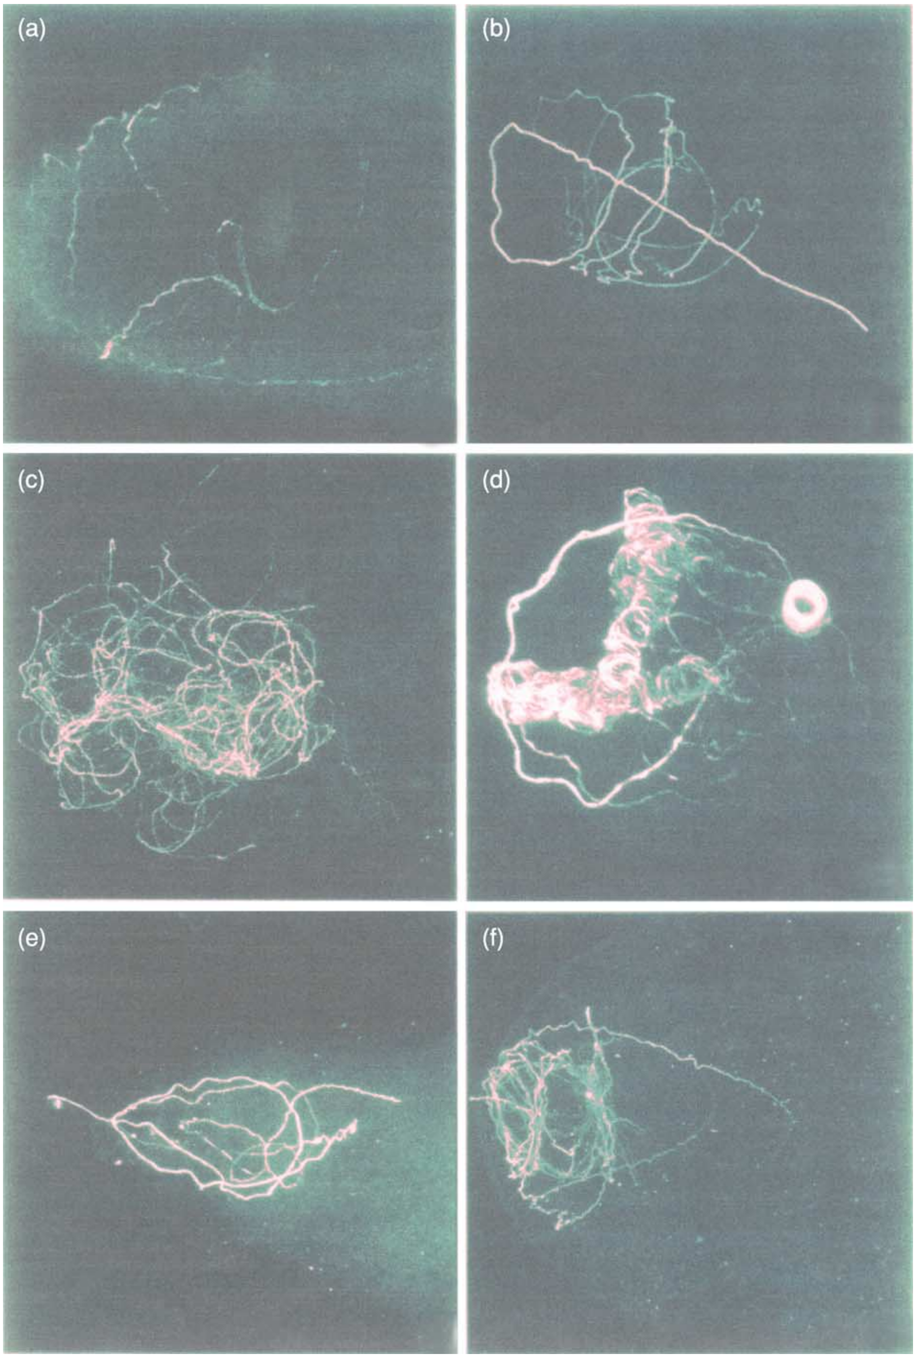

Figure 2 Sperm entry in *Drosophila*. Fertilization in six species of *Drosophila* observed using an anti-sperm polyclonal antibody. (a) *D. busckii*. (b) *D. simulans*. (c) *D. ezoana*. (d) *D. pachea*. (e) *D. bifurca*. (f) *D. wassermani*.

sperm types are capable of fertilization, as determined by direct measurement of sperm in the egg (Snook *et al*., 1994; Snook and Karr, 1998). Thus, the existence and maintenance of multipe sperm types remains an outstanding developmental and evolutionary conundrum. However, it is quite clear that the answer will lie in understanding why short sperm do not, or cannot, enter the egg.

1.6.4. Genetic Analysis: Fertilization Functions Identified by Parental Effect Mutations

In *Drosophila*, formation of the zygote and early embryonic development take place without any transcriptional activity and, thus, are essentially dependent on maternal gene products (mRNA and

proteins) delivered in the oocyte at the end of oogenesis. In comparison with the egg, the volume of the sperm cell is negligible and it contains virtually no cytoplasm. It is, thus, not expected to substantially contribute to the pool of gene products necessary for the formation of the zygote. It should be mentioned that it is unknown whether or not the gigantic flagellum, which could represents a potential source of paternal products, has any function for the zygote. However, aside from its obvious contribution of the paternal genome complement, the sperm delivers a centriole pair that is required for the assembly of the first MTOC of the zygote. Thus, a mutation that affects any step between fertilization and the formation of the zygote must exert its phenotype through a strict parental effect. These mutations can be either maternal or paternal effect mutations, and they usually induce embryonic death. Practically, most of them behave as female or male sterile mutations, in the sense that they do not produce viable progeny. However, developmental arrest can occur at various stages depending on the nature of the defects that affect the formation of the zygote. In some cases, the spermatozoon is not activated and the egg forms only polar bodies, just like an unfertilized egg. In other cases, the mutation can compromise the ability of one set of parental chromosomes to integrate into the zygote nuclei or to achieve the first nuclear cycle. Because of the gonomeric nature of the first division, the resulting embryos develop with the set of chromosomes that are not affected by the mutation. In practice, embryos develop as haploid or aneuploid embryos. Whereas aneuploid development arrests after a few nuclear divisions, haploid *Drosophila* embryos reach late embryogenesis but all die shortly before hatching. The fact that haploid development is lethal in *Drosophila* allows screening for parental effect embryonic lethal mutations.

In the sections below the various groups of characterized mutants depending on the biological process they affect during fertilization and/or the formation of the diploid zygote will be reviewed.

1.6.4.1. Acrosome Reaction/Sperm Activation

The processes by which the sperm locates, recognizes, and enters the egg have been described in details in several models such as echinoderms and mammals (Trounson and Bongso, 1996; Wolfsberg and White, 1996; Benoff, 1997; Vacquier, 1998; Wassarman, 1999; Serrano and Garcia-Suarez, 2001; Evans, 2002). Although ultrastructural studies have reported that insects, like higher animals, do possess an acrosome at the tip of their sperm, the molecular basis of sperm-egg recognition in insects is largely unknown. Insights have recently come with the identification of several *Drosophila* mutants that apparently affect sperm-egg interaction.

1.6.4.1.1. *casanova* In animals, sperm-egg recognition usually relies on the interaction of carbohydrate residues on the surface of the egg's vitelline membrane with complementary molecules on the plasma membrane of the sperm. In *Drosophila*, biochemical analysis have identified two distinct glycosidases at the surface of male gametes: β-*N*-acetylglucosaminidase and α-D-mannosidase (Cattaneo *et al*., 1997, 2002; Pasini *et al*., 1999; Perotti *et al*., 2001). *casanova (csn)* is a *Drosophila* male sterile mutant with a unique phenotype: *casanova* mutant males produce motile sperm that are stored in females but that fail to enter wild-type eggs (Perotti *et al*., 2001). Ultrastructural analysis of *casanova* sperm revealed that β-*N*-acetylglucosaminidase is absent from the spermatozoa membrane overlying the acrosome, where it is normally present. Although the *csn* gene has not been identified yet and probably does not encode this enzyme, this study suggests that a molecular sperm-egg recognition system (involving at least β-*N*-acetylglucosaminidase and its substrate β-*N*-acetylglucosamine) exists in insects, like in higher animals.

1.6.4.1.2. *sneaky* and *misfire* These two mutants are paternal effect lethal genes that display almost identical phenotypes (Fitch *et al*., 1998; Ohsako *et al*., 2003). *sneaky (snky)* and *misfire (mfr)* mutant males produce motile sperm that are able to enter the eggs but the sperm nucleus remains intact at the periphery of the egg cytoplasm (**Figure 3**). Cytological analysis of mutant sperm after fertilization suggests that the sperm activation defect, observed in both cases, is a consequence of the inability of these sperm to remove their plasma membrane after fertilization. Without plasma membrane breakdown, the sperm nucleus is not delivered to the egg cytoplasm and is thus unable to decondense its DNA. Furthermore, the paternal centrioles are not available for the egg and this prevents the migration of the female pronucleus and the potential division of maternal chromosomes. The molecular identification of *snky* and *mfr* should allow a better understanding of this crucial mechanism of sperm plasma membrane breakdown at fertilization.

1.6.4.2. Female pronucleus formation/migration Several mutants have been described that affect either the formation or the migration of the female pronucleus towards its male counterpart. In fact,

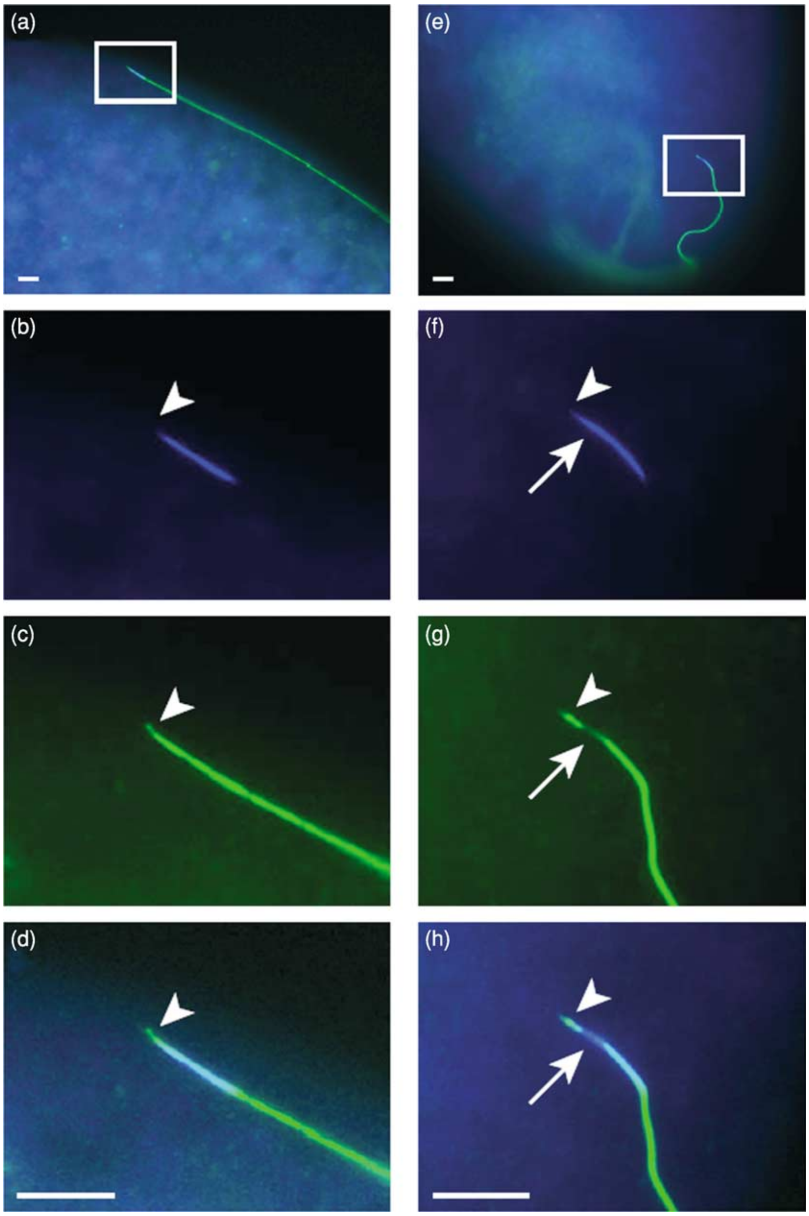

Figure 3 *misfire* (*mfr*) sperm in inseminated eggs. (a, high) and (e, low) magnification views of fertilization by *misfire* sperm (green; visualized using a sperm antibody), and DNA (blue; visualized by the DNA-specific dye, DAPI); (b, f), high magnification views of misfire sperm DNA (boxed regions in (a) and (e) showing needle-like morphology; (c, g) anti-sperm staining of (b, f) using a monoclonal anti-sperm antibody DROP 1.1; (d, h) the area of *mfr* sperm-inseminated eggs surrounded by the squares shown in panels (a) and (e), respectively. Arrowheads indicate the acrosome region; arrows indicate less stained region by DROP 1.1. Scale bar = 10 μm. (Reproduced with permission from Ohsako, T., Hirai, K., Yamamoto, M.T., **2003**. The *Drosophila* misfire gene has an essential role in sperm activation during fertilization. *Genes Genet. Sys. 78*, 253–266.)

all these mutants are allelic to genes involved in female meiosis and some of them are presented in this section.

1.6.4.2.1. α-*Tubulin 67C* and *polo* In some maternal effect alleles of α-*Tubulin 67C* and *polo*, female meiosis is abnormal and the female pronucleus is not properly formed (Komma *et al*., 1991; Riparbelli and Callaini, 1996). In the absence of a well-defined female pronucleus, the first spindle is assembled around paternal chromosomes. However, occasionally paternal chromosomes can undergo mitotic divisions and haploid androgenetic embryos (that invariably die) are observed. Presumably, because *polo* and α-*Tub 67C* are required for the assembly of normal mitotic spindles, the division of the male pronucleus is frequently impaired.

1.6.4.2.2. *KLP3A* and *wispy* *KLP3A* encodes a kinesin-like protein that is required both for male and female meiosis (Williams *et al*., 1995). In eggs laid by females homozygous for a strong allele of *KLP3A*, the meiosis is apparently normal and produces four haploid nuclei. However, none of these meiotic products migrate towards the male pronucleus, despite the presence of a sperm aster (Williams *et al*., 1997). Although an apparently normal spindle assembles around the paternal chromosomes in *KLP3A* eggs, the first mitotic division is invariably arrested in metaphase. *KLP3A* is, thus, required both for the female pronucleus to migrate but also to assemble functional mitotic spindles.

The phenotype of eggs from *wispy (wisp)* females is very similar to the KLP3A phenotype but in this case, the sperm aster is reduced and the spindle associated with the male pronucleus is abnormal with frequent dissociation of centrosomes. It has been shown that centrosomal proteins are reduced or absent in the centrosomes of *wispy* embryos. The *wispy* gene product is, thus, probably involved in the regulation of microtubule structures (Brent *et al*., 2000).

1.6.4.3. Sperm Chromatin Processing Before and After Fertilization

Spermiogenesis is a long and very complex process where the haploid spermatids produced by meiosis II differentiate into mature spermatozoa (see **Chapter 1.4**). Two major events occur during spermiogenesis that lasts several days in *Drosophila*. One obvious event is the formation of the flagellum by a process that involves the coordinated extension of the axoneme with the surrounding cell membrane and mitochondria derivatives. The other major event is the dramatic condensation of the spermatid nuclei. This is generally achieved (in mammals for example) by the partial or complete replacement of somatic histones (H2A, H2B, H3, and H4) with male germline specific transition proteins, sperm specific histones and/or protamines. In *Drosophila*, somatic histones are eliminated during spermatid condensation but the final molecular composition of the sperm chromatin in this species is still unknown.

The DNA in the *Drosophila* sperm nucleus is extremely compacted but it must decondense very rapidly once delivered in the egg cytoplasm at fertilization. The formation of the male pronucleus, in general, represents a very interesting situation for the study of chromatin assembly and remodeling, and many biochemical studies using various model organisms (including *Drosophila*) have focused on the purification of egg molecules capable of decondensing sperm nuclei *in vitro*. A classical example is nucleoplasmin, a protein abundant in amphibian eggs that has been shown to function as a histone chaperone *in vitro* (Philpott *et al*., 1991).

Drosophila is a particularly suitable organism to identify genes involved in the processing of sperm chromatin in the egg cytoplasm at fertilization. Because of the gonomeric nature of the first division, any defect in sperm chromatin processing is expected to induce haploid gynogenetic development of at least a fraction of the embryos. The following examples illustrate *Drosophila* as a promising model for the understanding of this fundamental aspect of fertilization.

1.6.4.3.1. *sésame* *sésame (ssm)* was originally obtained in a screen for X-linked female sterile recessive mutations. Homozygous *ssm*^{185b} females are completely sterile, independent of the genotype of the males used in the crosses. *sésame* is an embryonic lethal maternal effect mutation: mutant females produce normal eggs but the embryos that develop die just before hatching. These embryos die not directly because of the mutation but because of the fact they are haploid, containing only maternally-derived chromosomes. This phenotype is indicative of a defect of paternal chromosomes to integrate in the zygote nuclei and, thus, suggests a problem at fertilization. Haploid gynogenetic development of embryos is a phenotype that is found in two other parental effect mutants that will be described below. In eggs produced by *sésame* females, the male pronucleus is severely delayed in decondensation compared to wild-type (**Figure 4a** and **b**). The gonomeric spindle is organized only around the female pronucleus and the female chromosomes divide normally (**Figure 4c**). In contrast, the male pronucleus appears abnormally condensed and usually remains excluded from the first spindle (Loppin *et al*., 2000).

Interestingly, in eggs from *ssm* females, maternally provided core histones are not deposited in the chromatin of the male pronucleus, which suggests that the paternal DNA remains associated with sperm-specific chromosomal proteins in this mutant context (Loppin *et al*., 2001a). The *sésame* function is, thus, required for the assembly of nucleosomes in the male pronucleus. The *ssm* mutation, with its unique phenotype, represents the first genetic demonstration that the chromatin assembly in the male pronucleus is dependent on a maternal factor. *ssm* has been recently shown to be a point mutation in the *Hira* gene, which encodes a conserved member of the WD-repeat protein family (Loppin *et al*, unpublished data). In *Xenopus*, HIRA is critical for the assembly of nucleosomes independent of DNA replication (Ray-Gallet *et al*., 2002), a crucial

function as the male pronucleus must assemble chromatin prior to DNA replication. In *Drosophila*, *Hira* expression is not restricted to the female germline, and the *ssm*[185b] allele probably only affects the function of *Hira* at fertilization. New alleles should allow one to determine if *Hira* has a more general role in the assembly of chromatin independent of DNA replication.

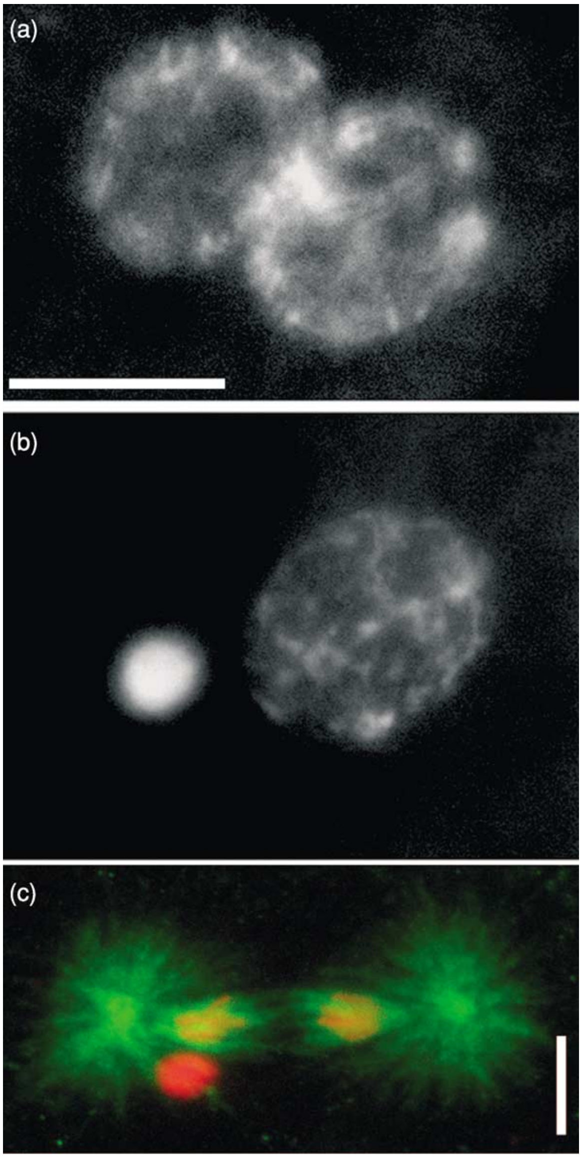

Figure 4 The *sésame* phenotype. Confocal images of fixed eggs stained with a DNA fluorescent dye. (a) Apposed pronuclei in a wild-type fertilized egg. (b) Pronuclei at the same stage in a fertilized egg laid by a ssm female. The small, bright nucleus on the left is the male pronucleus. (c) Anaphase of the first division in an embryo from a *ssm* female. The condensed male pronucleus (red, DNA) is excluded from the gonomeric spindle that contains maternally-derived sister chromatids (yellow embedded in spindle microtubules colored green). Scale bar = 10 μm.

1.6.4.3.2. *maternal haploid* *maternal haploid (mh)* is, like *sésame*, another maternal effect embryonic lethal recessive mutation. Historically, *mh* was the first mutant described to produce haploid embryos (Santamaria and Gans, 1980). Early haploid embryos do not present any major phenotype, with the exception that cellularization occurs after an extra round of nuclear division (Edgar *et al.*, 1986). Haploid embryos die later in embryogenesis and cuticle preparations of dead embryos reveal head involution defects and/or dorsal open phenotypes in all reported cases (Fuyama, 1984; Loppin *et al.*, 2000, 2001b).

Fertilization in eggs produced by *mh* females was more recently analyzed in order to understand the mechanism of paternal chromosome elimination from the developing embryos (Loppin *et al.*, 2001b). In contrast to *ssm* eggs, the male pronucleus in *mh* eggs fully decondenses and apposes to the female pronucleus, and both pronuclei are found within the gonomeric spindle. However, paternal sister chromatids are unable to separate at anaphase of the first zygotic mitosis (**Figure 5**). When female sister chromatids have fully separated during anaphase, the paternal chromatin lags behind on the metaphase plate. Paternal DNA, at least partially,

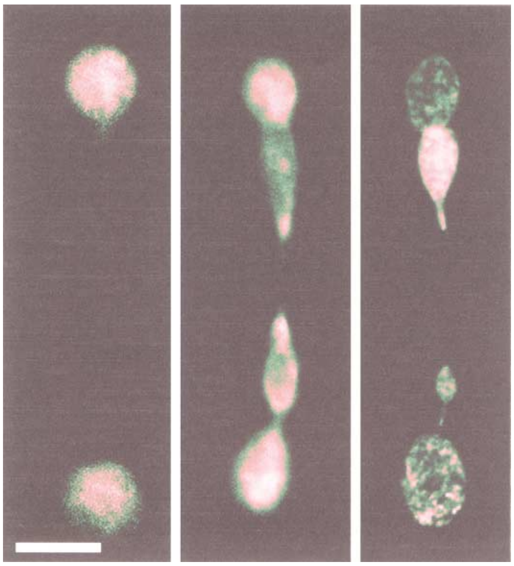

Figure 5 The *maternal haploid* phenotype. Confocal images of early embryos stained with a DNA fluorescent dye. Left panel: Late telophase of the first zygotic division in a wild-type egg. Middle panel: An embryo at the same stage from a *mh* female. The lagging paternal chromatin has formed a bridge between the two daughter nuclei containing the maternal chromatin. Right panel: An embryo from a *mh* female at the beginning of the second nuclear cycle. The haploid daughter nuclei are in interphase. Uneven segregation of paternal chromatin is clearly seen in this embryo. Scale bar = 10 μm.

replicates in *mh* eggs, as revealed by observation of a pericentromeric chromatin marker, but sister chromatids do not properly separate at the onset of anaphase. In telophase, the lagging paternal chromatin eventually forms a chromatin bridge and is torn apart by the traction of the spindle. The unequal segregation of paternal chromatin at the first division is responsible for the aneuploid development of a majority of the embryos, which usually die after a few nuclear divisions. Some of them (about 25%) manage to escape this early lethal phenotype as haploid gynogenetic embryos and die before hatching.

The *mh* phenotype demonstrates a maternal function that specifically controls the processing of paternal chromatin at fertilization. It is not clear whether *mh* directly affects the condensation of paternal chromosomes at the first division or the separation of sister chromatids. Alternatively, it is possible that *mh* is involved in sperm chromatin remodeling but with an associated mutant phenotype only detectable at the first mitosis. It is interesting to note that very similar effects on paternal chromosomes at the first division are observed for the paternal effect mutant *ms(3)K81* described below.

1.6.4.3.3. *ms(3)K81* *ms(3)K81* (*K81*) is the third mutant that produces haploid gynogenetic embryos but, in contrast to *sésame* and *maternal haploid*, *K81* is a strict paternal effect embryonic lethal mutant. Homozygous *K81* males do not present any apparent spermatogenesis defects: they produce motile sperm that fertilize eggs but the resulting embryos die. Similar to *mh*, most embryos from *K81* fathers (~90%) die after a few nuclear cycles but very few (<1 in 10^5) hatch as haploid gynogenetic embryos (Fuyama, 1984). The original *K81* allele (*K81*^{1}) was collected in the field in Japan but new deletion alleles were subsequently recovered (Yasuda *et al*., 1995). At the cytological level, the *K81* phenotype at fertilization is undistinguishable from the *mh* phenotype: paternal chromosomes are integrated in the gonomeric spindle but only maternal chromosomes divide correctly. It is interesting to note that the very same phenotype can be obtained from a maternal (*mh*) and a paternal effect (*K81*) mutant (**Figure 6**). It is reasonable to think that the *K81* phenotype is most probably due to a defect in sperm chromatin organization.

We have recently identified the gene responsible for the *K81* phenotype (B. Loppin, P. Couble and T. Karr, unpublished data). It is a small gene that contains a single exon of 555 bp with no intron that is specifically expressed in the male germline. Surprisingly enough, we have not found any ortholog of *K81* in the available database, even in the recently sequenced *D. pseudoobscura* and *Anopheles gambiae* genomes. *K81* has only been found in the closest relatives of *D. melanogaster* and the gene appears to rapidly evolve within the *melanogaster* subgroup.

K81 is, thus, a gene that is absolutely required for male fertility but that is paradoxally restricted to a few species. It is now established that many male-specific genes involved in spermatogenesis are among the most rapidly evolving genes (Vacquier *et al*., 1997; Ting *et al*., 1998; Tsaur *et al*., 2001; Swanson and Vacquier, 2002). The *K81* mutant phenotype is unique and suggests a defect in sperm chromatin organization or an aberrant epigenetic marking of the paternal genome during spermatogenesis.

1.6.4.3.4. *paternal loss* and *Horka* *paternal loss (pal)* is another strict paternal effect mutant that induces the loss of paternal chromosomes in a proportion of their progeny. Paternal chromosomes are lost at different frequencies depending on the chromosome, the fourth being the most frequently lost (~17%) whereas the Y is lost in less than 1% of embryos (Baker, 1975). It has been suggested that *pal* could encode a component of paternal chromosome centromeres (Baker, 1975). The *pal* gene product is a small basic protein of 121 amino acids that lacks significant homology with known proteins (Fitch *et al*., 1998), similar to the K81 protein (see above). The PAL protein localizes to spermatid and sperm nuclei and is, thus, probably a sperm chromosomal protein. The *pal* loss-of-function phenotype is not accompanied by any detectable defect of spermatid condensation, but its absence is critical for the stability of paternal chromosomes after male pronuclear formation (Fitch *et al*., 1998). An intriguing aspect of the *pal* phenotype is that paternal chromosome loss can occur as late as the syncytial blastoderm stage. The defect on the paternal chromosome is, thus, probably maintained through successive mitotic divisions by an epigenetic mechanism whose nature remains to be determined.

Fs(3)Horka (Hor) was originally isolated as a dominant female sterile mutant that induces meiotic defects and early embryonic development arrest (Szabad *et al*., 1995). In eggs laid by heterozygous females, the male and female pronuclei approach together but they do not divide. *Horka* also induces equational nondisjunction during spermatogenesis and possesses a dominant paternal effect that, similarly to *pal*, induces paternal chromosome loss during early embryonic development, with the exception of the Y chromosome. This suggests

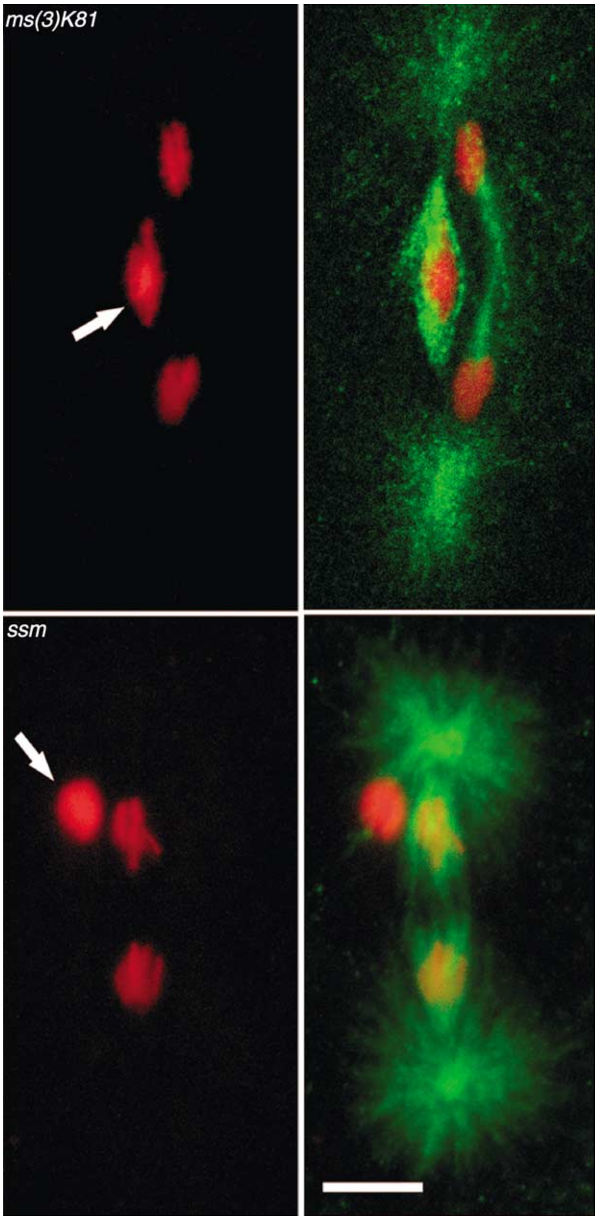

Figure 6 Comparison of mitotic phenotypes observed in *ms(3)K81* and *sesame* (*ssm*) mutants using anti-tubulin antibodies to label microtubules (green) and a DNA-specific flurochrome to label DNA (red). (Upper panels) Mitotic defect resulting from fertilization by *ms(3)K81* sperm displaying highly condensed paternal DNA of the male pronucleus (arrow). (Lower panels) *ssm* eggs fertilized by wildtype sperm displaying highly condensed maternal DNA of the female pronucleus (arrow). (Adapted from Loppin, B., Docquier, M., Bonneton, F., Couble, P., **2000**. The maternal effect mutation sesame affects the formation of the male pronucleus in *Drosophila melanogaster*. *Devel. Biol.* *222*, 392–404.)

that *Horka* could be required for normal function of the centromere, and the identification of the *Horka* gene product should allow testing of this hypothesis.

1.6.4.4. Cell Cycle Regulation

In this last section several mutants that do not exactly affect fertilization are grouped but instead control some aspects of the early mitotic cycles that take place immediately after pronuclear apposition. Since the functions affected by these mutations are critical for the completion of the cell cycle, defects are observed as early as the pronuclear stage.

1.6.4.4.1. *giant nuclei, plutonium*, and *pan gu* These three mutations are maternal effect embryonic mutations that affect the coupling of DNA replication and mitosis. *giant nuclei* (*gnu*), *plutonium* (*plu*), and *pan gu* (*png*) (Freeman and Glover, 1987; Shamanski and Orr-Weaver, 1991) all induce, through maternal effect, the formation of giant nuclei in unfertilized eggs or early embryos. The formation of giant nuclei results from the successive rounds of DNA replication that take place without mitosis. In unfertilized eggs, the female meiotic products all become giant, whereas in fertilized eggs this mutation also affects the male pronucleus. It has been recently shown that these three gene products coordinate the rapid succession of S-M phases in the early embryos by ensuring adequate Cyclin B protein level (Lee *et al.*, 2001, 2003). *png* encodes a serine/threonine protein kinase (Fenger *et al.*, 2000), and *plu* and *gnu* encode small, novel proteins (Elfring *et al.*, 1997; Renault *et al.*, 2003). PNG, Plu, and GNU constitute a novel protein kinase complex that specifically regulates S-M cell cycles.

1.6.4.4.2. *fs(1)Ya (Ya)* *fs(1)Ya* (*Young arrest*) is a maternal effect mutation that induces an arrest of development immediately after meiosis (Lopez and Wolfner, 1997). In arrested eggs, the pronuclei are close to each other, but their chromatin looks abnormally condensed and a normal spindle is not formed (Lin and Wolfner, 1991). *Ya* encodes a nuclear lamina protein that localizes to the nuclear lamina of both male and female pronuclei, as well as polar bodies. Interestingly, it has been shown recently that the YA protein is also able to bind chromatin through its interaction with DNA and histone H2B (Yu and Wolfner, 2002). This suggests that YA could regulate the condensation state of nuclei through a direct interaction between nuclear lamina and chromatin. It also raises the possibility that YA regulates the transition from meiosis to mitosis.

1.6.5. *Wolbachia*-Mediated Cytoplasmic Incompatability

Wolbachia are Gram-negative bacteria that are extraordinarily wide-spread in the animal kingdom,

particularly invertebrates. Estimated to infect 20–75% of all insects (now estimated over one million species), they also infect numerous noninsect invertebrates including spiders, mites, and various nematode species that cause diseases in humans (Werren, *et al*., 1995a, 1995b; Jeyaprakash and Hoy, 2000). *Wolbachia* are obligate intracellular microbes that cannot be cultured *in vitro* and, therefore, relatively little is known about their life-history traits, evolutionary history, and molecular biology. The unique biology of *Wolbachia* has attracted a growing number of researchers interested in questions ranging from the evolutionary implications of infection to the use of this agent for pest and disease control.

Wolbachia are closely related to the *Rickettsia*, microbes that cause numerous diseases of mammals, including humans. Molecular phylogenies based upon 16S rDNA and other gene sequences indicate a close relationship among these taxa and places the genus *Wolbachia* as a sister taxon to *Ehrlichia*, and within the clade linking *Ehrlichia*, *Wolbachia*, and *Rickettsia*. However, mapping of associated biological traits onto the phylogeny reveals that *Wolbachia* have secondarily specialized in manipulation of host reproductive biology and simultaneously lost their mammalian pathogenicity. *Wolbachia* is unique among members of this clade in that it does not cause mammalian disease and specifically targets and manipulates host reproductive processes, and this, consequently, represents an important evolutionary novelty.

The enormous diversity of species infected by *Wolbachia* and the manipulation of specific life history characters reflects a long history of coevolution within the host. As an obligate endosymbiont, *Wolbachia* must survive in an intracellular environment that presents two challenges: first, the bacteria must somehow manipulate the host immune response in a manner that renders that response ineffective (or even beneficial) and, second, replication of the bacteria must be integrated with the host environment such that replication and proliferation take place in the appropriate cellular environment. The phenomenal success of this organism in colonizing diverse arthropod lineages is testimony to its ability to solve these linked problems.

The astonishing ability of *Wolbachia* to manipulate host reproductive biology to foster their own propagation – feminization and parthenogenesis, androcidal effects, and cytoplasmic incompatibility – reflects extensive, high level integration of the parasite's biology with that of its host. Many members of the Hymenoptera (wasps, bees) undergo haplo-diploid development: fertilized eggs develop as diploid females, unfertilized eggs develop as haploid males (see **Chapter 3.13**). *Wolbachia* also induce parthenogenesis by "gamete duplication" that results in a diploid eggs. Among isopods, *Wolbachia* infection suppresses the development of an androgenic gland necessary for masculine differentiation. Androcidal, or male-killing, *Wolbachia* infections occur in Lepidoptera and Coleoptera, and, more recently, has been found in *Drosophila*. Thus, despite displaying a general facility to infect a wide variety of arthropods, *Wolbachia* also has the ability to control complex components of host development. This suggests that the various *Wolbachia* strains have sufficient history in current host species to have evolved mechanisms, which target these very diverse reproductive biology systems in their specific hosts.

1.6.5.1. Cytoplasmic Incompatibility: Sperm-Mediated Egg Lethality

Cytoplasmic Incompatibility (CI) was first recognized by the failure of certain intra- and interstrain crosses between and among various insect taxa (review: Stouthamer *et al*., 1999). In the most general case, uninfected females mated to infected males fail to produce viable progeny. In all cases so far studied, CI is manifested as the failure of eggs to hatch. Interestingly these eggs are fertilized, negating the trivial explanation that incompatible crosses result from fertilization failure. A schematic view of this is shown in **Figure 7** along with images of fertilization in both wild-type and CI crosses. The ramificatons of this process are clear – infected females win out over uninfected females 2:1 and, eventually, all other factors being equal, will completely replace the uninfected population.

CI results in early egg lethality following sperm entry (Callaini *et al*., 1996, 1997; Lassy and Karr, 1996). The earliest observed defects in CI crosses are chromosomal abnormalities during the initial zygotic division following fertilization. Developmental anomalies at later stages of development also occur, presumably as a result of this very early defect (**Figure 7**). Neither the nature of these differences nor their origins during development are yet known. However, it is clear that the developmental defects observed must have arisen earlier in the male during spermatogenesis for the following reasons: (1) an incompatible cross occurs between an infected male and an uninfected female and, therefore, the female has a less significant role in the expression of CI; and (2) mature sperm from infected males are devoid of *Wolbachia* (Snook *et al*., 2000). However, because the testes, where sperm are produced, harbor the majority of *Wolbachia*, sperm develop in an

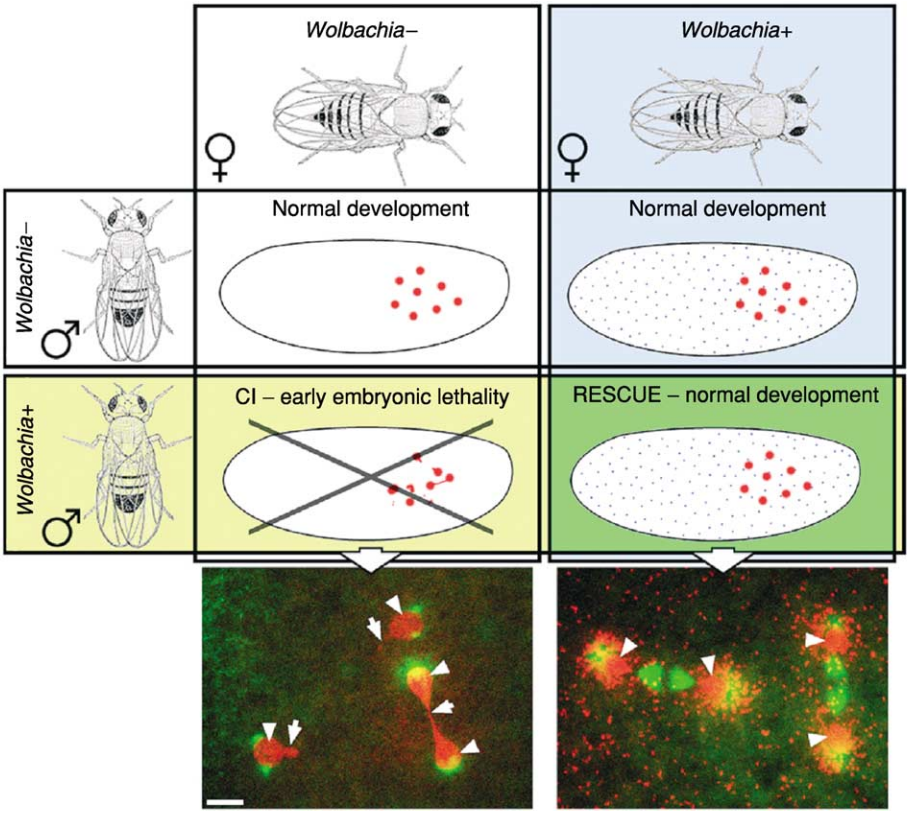

Figure 7 Cytoplasmic incompatibility induced by *Wolbachia*. There are four different mating combinations between infected and uninfected males and females. Infected females (blue) produce infected offspring that develop normally regardless of paternal infection status. Uninfected males mate successfully with both infected and uninfected females. However, infected males (yellow) mated to uninfected females produce some embryos with early embryonic lethality, characterized by defects in early mitotic divisions (CI, lower left) most often observed as defects in chromosome segregation during late telophase (nuclei, arrowhead). These defects are rescued when the same infected males are mated to infected females (Rescue, lower right). *Wolbachia* are seen as small punctuate dots, with high concentrations associated with astral microtubules. Red = DNA, Green = tubulin. Scale bar = 10 mm.

infected cellular environment and, therefore, *Wolbachia* must exert their effect(s) on sperm during spermatogenesis.

1.6.5.2. Models for CI

How do these curious microbes affect sperm function at such a crucial stage of development? Currently no single model yet explains CI. Three aspects of the biology of *Wolbachia*-induced incompatibility complicate attempts to produce a coherent picture: (1) sperm are altered, or modified so that they cannot, or can only poorly function when fertilizing uninfected eggs; (2) *Wolbachia* somehow "rescue" the sperm defect (i.e., crosses between infected males and females infected with the same strain are viable); and (3) distinct strains of *Wolbachia* can cause bidirectional CI. Thus, any complete model for CI must account for all these phenomena.

Work from a number of laboratories suggests that *Wolbachia* acts to alter sperm chromatin, resulting in a delay in or blockage of the proper formation of a male pronucleus (Callaini *et al.*, 1996, 1997; Lassy and Karr, 1996) (see **Figure 6**). As the early events of fertilization occur very rapidly, small perturbations in the kinetics of chromatin remodelling that must occur during this time, could result in failure of the two pronuclei to properly fuse, "diploidize", and form a viable zygote. Support for this model has come from cytological studies showing aberrant paternal chromosomes that fail to properly align along the first mitotic spindle. Such kinetic models are consistent with the data so far, but as yet do not explain how *Wolbachia* in the egg rescue these "kinetic" defects or how different strains cause different kinetic effects. These first molecular clues to the CI mechanism are consistent with a "kinetic" model of CI that suggested *Wolbachia* affect the relative timing of the events following sperm entry (Tram and Sullivan, 2002) (see below). Although these studies have clearly delineated the

spatio-temporal aspects of the expression of CI, more work is needed to identify the molecular components involved and the specific cellular pathways effected.

1.6.6. Fertilization in Non-Drosophiliids

Fertilization in a variety of non-Drosophiliid species has been studied and, for the most part, the basic overall picture of fertilization is similar to that found in *Drosophila* (Kawamura, 2001). In fact, for obligate sexual species, the "gonomeric" fertilization pattern appears to be universal, accepting the fact that exceptions will always be found when defining patterns and principles for such a diverse group of animals. A few examples of fertilization, zygote formation, and early development in a wide range of insects spanning numerous orders of the Insecta are provided below.

1.6.6.1. Fertilization in *Athalia rosae*

The turnip sawfly, *Athalia rosae*, is a hymenopteran unique in fertilization biology for being the only insect to date, in which *in vitro* fertilization (IVF) has been achieved (Sawa and Oishi, 1989a, 1989b; Oishi *et al*., 1993; Hatakeyama *et al*., 2000). These pioneering studies unfortunately have not led to similar successes in other insect systems, particularly *Drosophila*, where an efficient *in vitro* system would provide not only a wealth of research possibilities, but could eventually, in conjuction with cryopreservation of sperm, become a useful alternative, or complement to the stock centers. Nonetheless, the sawfly system paves the way for future studies of *in vitro* fertilization in insects, a worthy goal with high payoff for both basic and applied research.

Athalia eggs can only be successfully fertilized using intra-cytoplasmic sperm injection (ICSI), which is a practical limitation for cell biologists interested in exploiting such systems in order to study the basic cellular and molecular mechanisms of fertilization. For example, a robust IVF system could be used to acquire large numbers of synchronized eggs, a requirement for biochemical studies of kinase signalling cascades during zygote formation.

1.6.6.2. Fertilization in *Sciara coprophila*

While the major thrust in fertilization research of insects has understandably focused on *Drosophila*, fertilization and early development of the fungal gnat, *Sciara coprophila*, has recently been examined at the cell biological and molecular levels (de Saint Phalle and Sullivan, 1996; de Saint Phalle and Sullivan, 1998). In *S. coprophila*, both sexual and parthenogenetic development can be studied in the same animal, as females can be induced to lay eggs with or without mating. Early events during these stages were documented using antibody staining of fixed eggs (**Figure 8**), and molecular markers to follow the fate of chromosomes following fertilization. Parthenogenesis occurs at low frequency and unfertilized embryos initiate development without centrosomes. Thus, comparison with fertilized eggs of spindle assembly and mitosis in the presence and absence of centrosomes could be performed (de Saint Phalle and Sullivan, 1998). In both cases, although functional mitotic spindles are formed that successfully proceed through anaphase and telophase, forming two daughter nuclei separated by a midbody, significant differences were observed (**Figure 8**). The spindles assembled without centrosomes in unfertilized eggs are anastral, and it is likely that their microtubules are nucleated at or near the chromosomes. An uneven distribution of nuclei suggested a role for centrosomes. Although mitotic spindles undergo anaphase B and successfully segregate sister chromosomes, without centrosomes, the distance between the daughter nuclei in the next interphase is greatly reduced. This suggests that centrosomes are required in order to maintain nuclear spacing during the telophase to interphase transition.

Similar to *Drosophila*, nuclei in fertilized centrosome-bearing embryos maintain an even distribution as they divide and migrate to the cortex. In embryos lacking centrosomes, nuclei collide and form large, irregularly shaped DNA-containing clusters, and they never successfully migrate to the cortex. Presumably, this phenotype is a result of failure to form astral microtubules in parthenogenetic embryos lacking centrosomes. Following an indeterminate number of mitoses, the eggs invariably die due to aneuploidy and DNA clumping, suggesting that functional centrosomes are essential for viability in this organism.

1.6.6.3. Centrosome Inheritance in Haplo-Diploid Development

Sex determination in hymenopterans is haplodiploid, which usually means that haploid males develop from unfertilized eggs and diploid females are produced following fertilization. Because the sperm is thought to provide the basal body that becomes the centrosome and microtubule organizing centers (MTOCs), it has been somewhat of a mystery as to when, where, and how these crucial cell organelles form during haploid development. Although this issue was investigated in the *Sciara*

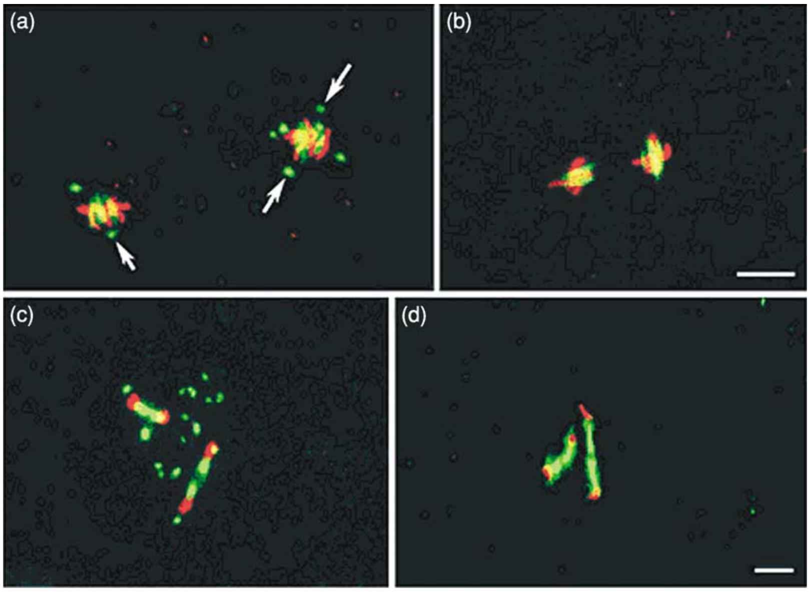

Figure 8 Unfertilized embryos do not possess MTOCs. Nuclear cycle 2 embryos are stained for their DNA (red) and microtubules (green). (a) In a fertilized embryo, two of the MTOCs (arrows) are associated with spindle poles while the others surround the metaphase plate. (b) In the equivalently staged unfertilized embryo, no MTOCs are present, and by counting the chromosome arms it can be seen that the nuclei are haploid. This may be why unfertilized nuclei seem smaller. (c and d) Telophase of nuclear cycle 2 in fertilized and unfertilized embryos, respectively. While both exhibit robust midbodies, no MTOCs are present in the unfertilized embryo. Scale bar = 10 µm.

system (see above), these studies suffered from a lack of direct observation, instead relying on fixed material that can only give a static view of the process as described below.

1.6.6.3.1. Real-time visualization of fertilization and centrosome inheritance A significant breakthrough in our understanding of haploid development in hymenopterans has come from real-time observations using microinjection of fluorescently labeled tubulin into living eggs. Coinjection of a DNA-specific fluorescent dye allowed contemporaneous visualization of both DNA and microtubule dynamics during the very early stages of zygote formation. Thus, fertilization and zygote formation in both haploid and diploid eggs were examined in *Nasonia vitripennis* as shown in Figure 9.

1.6.6.3.2. Mechanism of CI in *Nasonia*: The "slow-motion" model An intriguing variation on this theme is the effect of *Wolbachia* on the system: uninfected eggs that would normally develop as haploid males, instead develop as diploid females. In fact, studies of fertilization in hymenopterans were prompted, in part, by the unusual effect of *Wolbachia* on sex determination as mentioned above, and on understanding the origin and mechanism of early development in the absence of fertilization by sperm. These studies have led to a deeper understanding of centrosome formation and inheritance in both fertilized and unfertilized eggs in general, and lent support to a kinetic model of CI. Although beyond the scope of this review, the model basically proposes that *Wolbachia* act on sperm in such a manner as to delay sperm nuclear envelope breakdown, thus preventing the proper course of events needed for formation of a proper gonomeric spindle. This provocative model will hopefully spawn additional studies designed to test this, and other models.

1.6.6.4. Fertilization in Coleoptera, Lepidoptera, and Orthoptera

Fertilization in a coleopteran, *Aleochara bilineata*, a parasitic beetle, a lepidopteran, *Bombyx mori* (common silkworm), and an orthopteran, *Gryllus bimaculata* (common cricket), has been described and these cases are used here to illustrate the broad basic features of fertilization in these groups. It is clear that although these taxa represent very diverse groups that diverged over 300 million years ago, they maintain common features of fertilization, which may explain, atleast in part, the unprecedented success of insects.

1.6.6.4.1. *Aleochara bilineata* Coleopterans comprise the largest order of insects, with at least

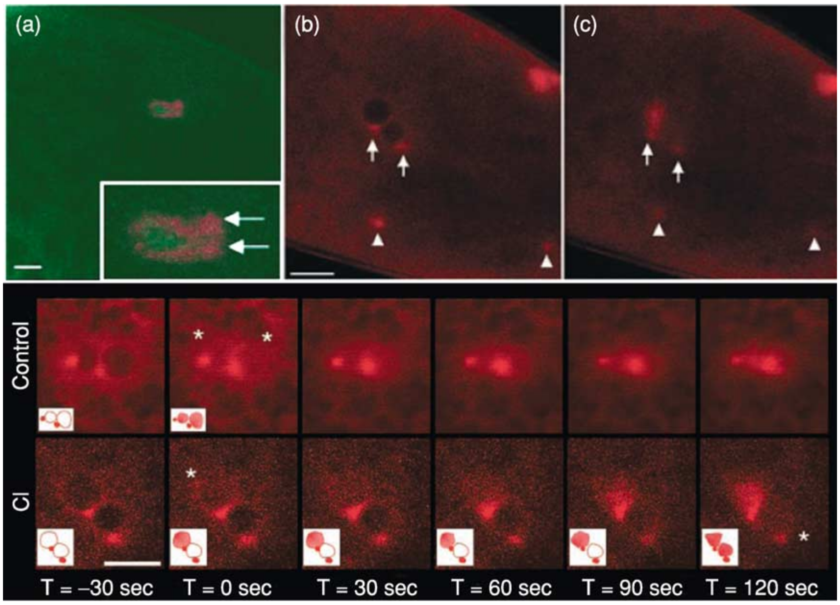

Figure 9 CI in *Nasonia vitripennis* (panels (a), (b), (c)). (a) CI embryo injected with rhodamine-tubulin (red; labeling centrosomes and nuclear periphery) and Oligreen (green; labeling DNA) showed that sperm from a *Wolbachia*-infected male is rod-shaped and associated with two paternally derived centrosomes (arrows, inset). Scale bar = 5–8 μm. (b) In CI embryo, injected with rhodamine-tubulin, pronuclei were apposed and centrosome separation (arrows) occurred normally. Maternally derived centrosomes (arrowheads) were present in the cytoplasm. (c) In same embryo as in (b), T = +510s, paternally derived centrosomes (arrows) set up mitotic spindle; maternally derived asters degenerate. (Lower panels) Real-time visualization of fertilization and centrosome inheritance in *N. vitripennis*. Relative timing of nuclear-envelope breakdown (NEB) was disrupted in CI embryos. NEB was assessed by time-lapsed confocal microscopy of 0- to 1-h embryos injected with rhodamine-tubulin. When the nuclear envelope was intact, the nucleus appeared as a black circle surrounded by a ring of red (rhodamine-tubulin) (T = 30 s). At NEB (indicated by ∗), rhodamine-tubulin invaded the nucleus (control, T = 0 s; CI, T = 0 s and T = 120 s). (Insets) Schematized interpretation of NEB. (From Tram, U., Sullivan, W., **2002**. Role of delayed nuclear envelope breakdown and mitosis in *Wolbachia*-induced cytoplasmic incompatibility. *Science 296*, 1124–1126.)

350 000 species described and a world-wide distribution. The staphiliniid beetles have been heavily studied as a model system for sexual selection and sperm competition (Gack and Peschke, 1994; Benken *et al*., 1999). Although distantly related to *Drosophila*, *A. bilineata* males also produce relatively large sperm (∼1 mm in length). Interestingly, the entire sperm enters the egg and is restricted to a single quadrant, presumably where the sperm enters (**Figure 10**; K. Peschke and T. Karr, personal communication). This supports the idea that total sperm entrance occurs across a very wide spectrum of insects, and it will be of interest to determine if this pattern of sperm usage occurs in additional members of this highly speciose group of insects.

1.6.6.4.2. *Bombyx mori* The common silkworm has been extensively studied over the past century for its obvious commercial value. Fertilization (**Figure 11**) has been described (Kawamura, 1978, 1979) and recently reviewed in the context of fertilization in other systems such as the sea urchin and *Ascaris* models (Kawamura, 2001). Pronuclear formation, migration, and spindle formation is as described in *Drosophila*, and provides perhaps one of the best examples of gonomeric spindle structure ever recorded (Kawamura, 1978).

As in most lepidopterans, *Bombyx* males produce two sperm types – eupyrene, containing a C-complement of DNA, and apyrene, devoid of DNA. The existence and persistence of these two sperm morphs is an outstanding problem in developmental and evolutionary biology that has yet to be resolved. However, recent work has shown a role for apyrene sperm in double matings of females to apyrene-only males and males that are sterile but contain eupyrene sperm. This is the first direct demonstration for a role of apyrene sperm in assisting fertilization.

1.6.6.4.3. *Gryllus bimaculata* Orthopterans, including crickets and grasshoppers, are represented by more than 20 000 species with a world-wide distribution, and include historically difficult pests such as the locust. The cricket, *Gryllus bimaculata* has been for many years a favorite for the study of sperm competition and related life-history traits (Simmons, 1987; Simmons and Siva-Jothy, 1998;

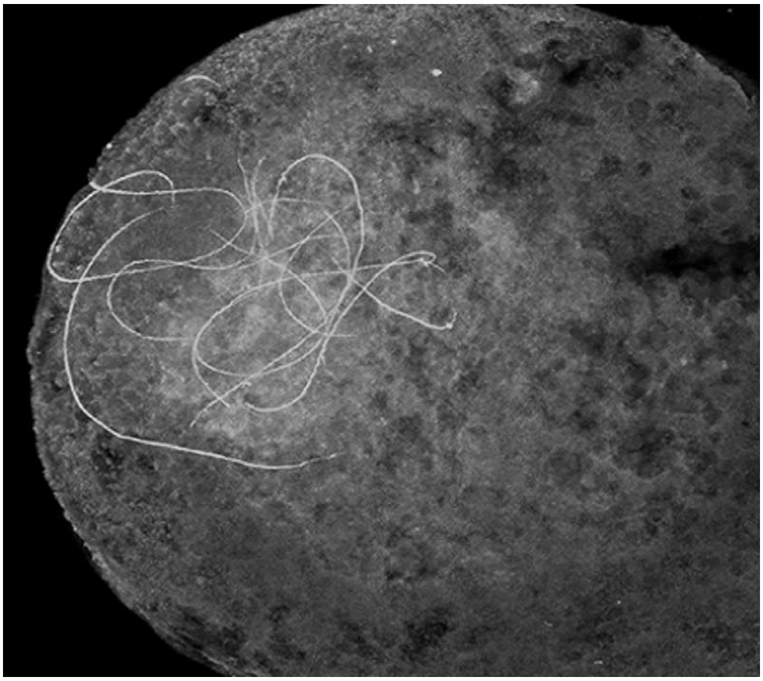

Figure 10 *Aleochara bilineata* fertilization. Indirect immunofluorescence using an anti-sperm polyclonal antibody shows the approximately 1 mm long sperm (thin bright coil on left side) inside a roughly spherical egg (T. Karr and K. Petschke, unpublished data).

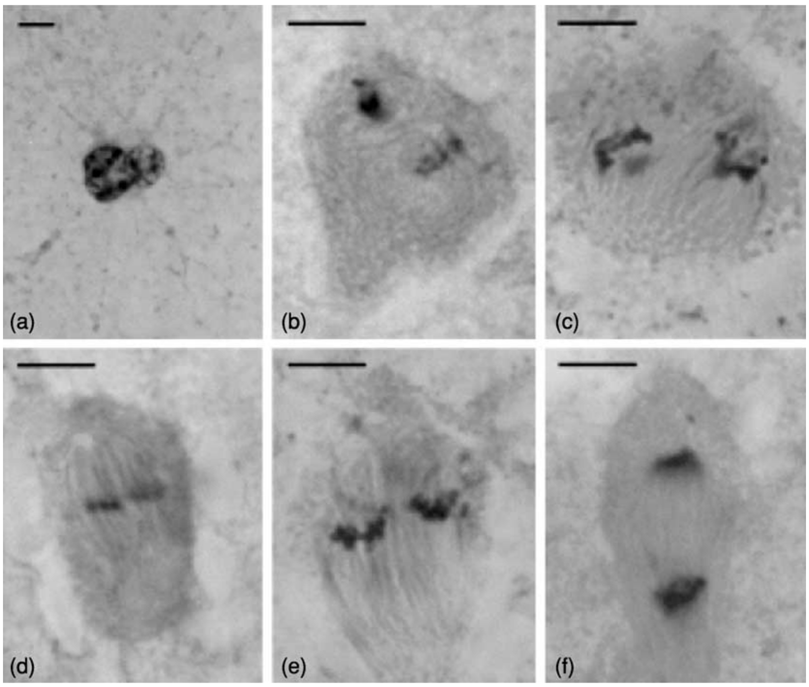

Figure 11 *Bombyx mori* fertilization. The first cleavage mitosis in the silkworm. (a) Union of male and female pronuclei. (b) Prophase. Two small spindles in the paternal and maternal pronuclei take rectangular positions. Two serial sections are superimposed. (c) Late prometaphase. Two independent spindles from the two pronuclei assume a parallel position. (d) Metaphase. Paternal and maternal chromosome groups are separate on a spindle. (e) Early anaphase. Two chromosome groups are still separate. (f) Telophase of the first cleavage. Chromosome groups are fused on the spindle poles (karyogamy). (a) Scale bar = 20 μm; (b–f) scale bar = 10 μm. (From Kawamura, N., **1978**. The early embryonic mitosis in normal and cooled eggs of the silkworm, *Bombyx mori*. *J. Morphol.* *158*, 57–72; reprinted by permission of John Wiley & Sons Inc.).

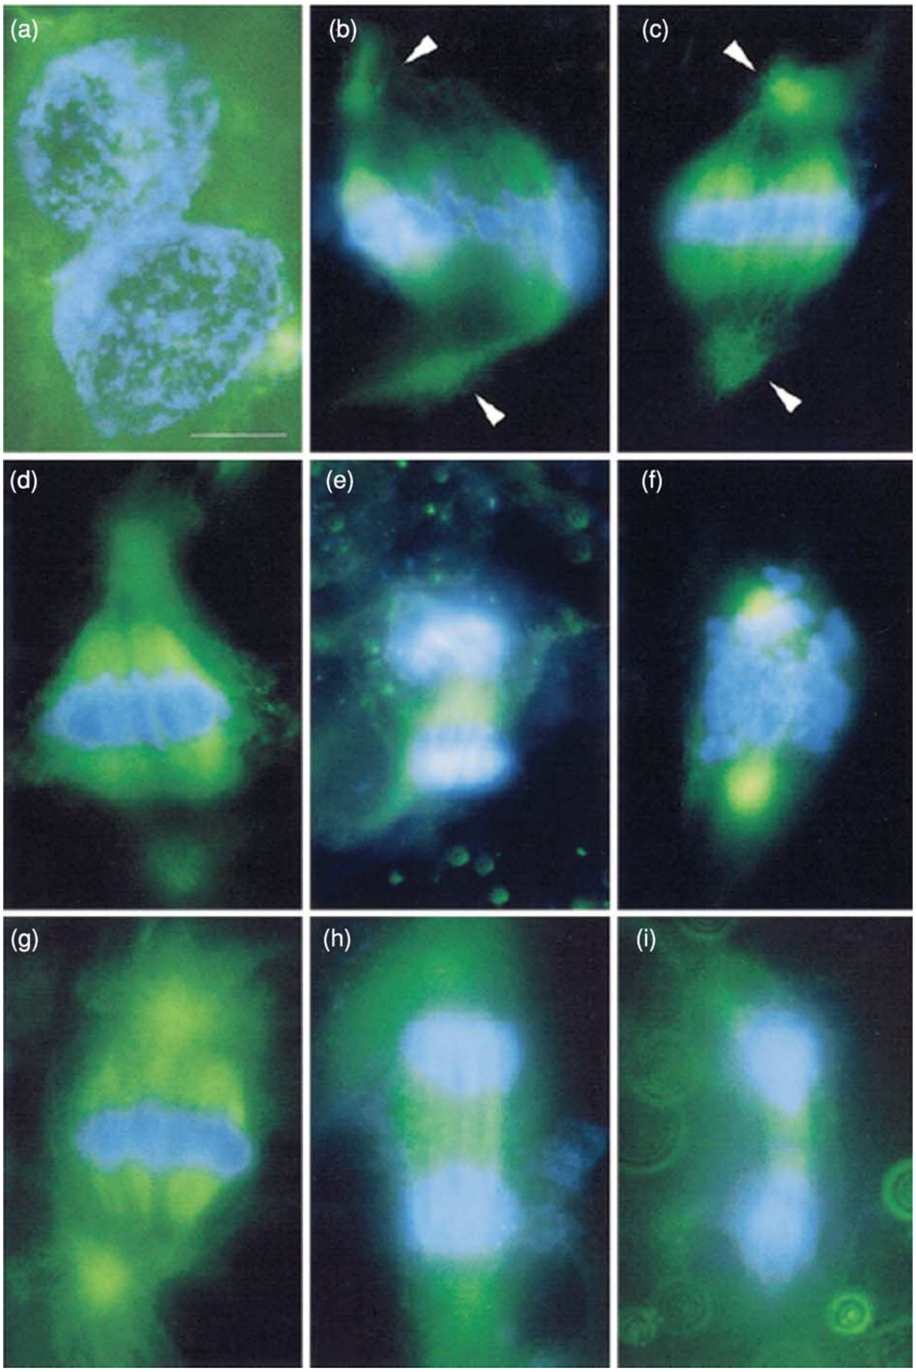

Figure 12 *Gryllus bimaculatus* fertilization. The first (a–e) and second (f–i) cleavage mitosis displayed by immunostaining for tubulin (green signal) and by Hoechst staining (blue signal) in squash preparations respectively. (a) Union of female and male pronuclei. (b) Prophase of the first cleavage mitosis. A spindle is formed in each of the parent pronuclei. Note the tubulin bundles (arrowheads) protruding from each of the spindle poles toward the opposite direction. (c) Metaphase. Spindles from parent pronuclei are still separate, while an astral center (arrowhead) is formed at each of the spindle poles. (d) Early anaphase. Astral centers become indistinct. (e) Telophase of the first cleavage mitosis. Parent chromosome groups are fused at the spindle poles. Astral centers disappear. (f) Prophase of the second cleavage mitosis. Strong signal of MTOC appears at two sides of the nucleus. (g) Metaphase. Asters radiate from both spindle poles. (h) Anaphase. Asters and MTOCs are becoming indistinct. (i) Telophase. Strong signal of microtubules disappears. Scale bar = 10 μm. (Reprinted with permission from *J. Morphology*.)

Tregenza and Wedell, 1998, 2002). It is, therefore, of great interest to molecular ecologists and animal behaviorists to understand the basis for sperm competition, and clearly sperm function during fertilization could play a role. Although we know little about fertilization in orthopterans, fertilization in *Gryllus* (**Figure 12**) was recently described (Sato and Sato, 2002). *Gryllus* eggs are similar in shape to *Drosophila* but usually 3–4 times longer. Polyspermic fertilization occurs in this species, with as many as 3–4 sperm found immediately adjacent to the micropyle, the point of sperm entrance. A single sperm (from this peripheral position) is "chosen" and moves into the interior region of the egg, forming a microtubule-rich "fertilization island", where the sperm nucleus decondenses and presumably replicates its DNA. The newly formed male and female pronuclei then move together and form the gonomeric spindle. Thus, many features of *Gryllus* fertilization are similar if not identical to *Drosophila*. One interesting difference is the presence of polyspermy, which is a regular occurrence in many insect species. However, polyspermy in *Drosophila* rarely occurs with some notable exceptions (Snook and Karr, 1998). Comparative work in polyspermic species such as *Gryllus* should prove fruitful in understanding the basis of polyspermy and its evolution.

1.6.7. Future Directions

Classical genetic analyses of *Drosophila* fertilization will continue to make significant contributions to the general field of fertilization biology and, in particular, to provide a more global view of this important and central process. However, as with any general approach to scientific investigation, genetic analyses will benefit greatly from additonal avenues of research that both complement and extend genetic approaches. For example, the recent microarray and bioinformatics approaches are currently being used to define the testis transcriptome (Andrews *et al*., 2000; Oliver, 2002a, 2002b; Oliver and Leblanc, 2003; Parisi *et al*., 2003). One area that is especially well-suited to do this is the proteomics of sperm, an area that is only now being investigated intensely (Graner *et al*., 1994; Feder *et al*., 1999). The idea is that knowledge of the complete sperm proteome will identify proteins with potential paternal effects. In theory, any protein delivered to the sperm could be a potential gene of paternal effect. To this end, we have recently initiated a whole cell mass spectrometry study of *D. melanogaster* sperm, and have identified more than 350 putative sperm proteins. An initial evolutionary analysis of the sperm proteome identified more than 190 orthologous genes in *D. pseudoobscura*, suggesting that these genes are conserved between these distantly related flies. Thus, a new data set now exists for future genetic and functional studies of fertilization in *Drosophila*.

1.7 Dosage Compensation

J C Lucchesi, Emory University,
Atlanta, GA, USA

1.7.1. Introduction

Insects exhibit a veritable plethora of mechanisms for determining the sex of their developing embryos (reviews: Marin and Baker, 1998; Normark, 2003) (see also **Chapter 1.1**). The majority of these mechanisms can be grouped into three broad categories. Most prevalent in all orders of insects – except Thysanoptera and Hemiptera – is diplodiploidy: males and females inherit one haploid genome from each of their two parents, and the maternal and paternal members of each homologous chromosome pair are transmitted with equal probability to the next generation. Some insects exhibit haplodiploidy whereby males transmit only their mother's genome to their offspring. In Thysanoptera, Hymenoptera, some Hemiptera, and some Coleoptera, males develop from unfertilized eggs; in other species of Hemiptera and Coleoptera, and in some species of Diptera, males develop from fertilized eggs but the paternal genome is eliminated or inactivated in the soma during early development and only the maternal genome is transmitted through the sperm. The third major category of sex-determining mechanisms is parthenogenesis. In the most common form, unfertilized eggs that produce females and males are never present; diploidy of female embryos is assured either by the mitotic origin of the eggs or by some postmeiotic event that leads to a doubling of the haploid complement. More rarely, females mate with males of closely related species but the sperm pronucleus never fuses with that of the egg; alternatively, fusion of the pronuclei occurs and the paternal genome is active in the soma but is eliminated during oogenesis. To further complicate matters, some insects alternate between two of the systems just outlined, either on a regular basis or as a consequence of some exogenous factors. Of interest is the fact that diplodiploidy and haplodiploidy never alternate although either of these mechanisms can alternate with parthenogenesis.

In the majority of diplodiploid species, the difference between the two sexes is based on the presence of special chromosomes that are called the "sex chromosomes." All of the other chromosomes that are present in the genetic material are called "autosomes" to distinguish them from the sex chromosomes. The difference in the sex chromosomes present in males and females is not the same in all species: in dipteran species, for example, females have two sex chromosomes that are identical in shape and genetic content called the X chromosomes; males have only one X chromosome and, instead of a second X, they have a sex chromosome that is different in shape and genetic content called the Y chromosome. In some Orthoptera, the only sex chromosome present in males is the X chromosome. In most Lepidoptera, males have two identical sex chromosomes and it is the females that have only one of these chromosomes and another sex chromosome that is different. To emphasize this point, the sex chromosome that is found in both sexes in these particular species is called the Z chromosome and the other sex chromosome, found only in females, is called the W chromosome. In any species, the sex that produces two different types of sex cells with respect to their sex chromosome content is said to be "heterogametic"; the other sex is termed "homogametic."

The sex chromosomes are responsible for determining the sex of an individual through the function of some of the genes that they carry (for a review see **Chapter 1.1**). Of course, there must exist a difference in these sex-determining genes between the

fertilized eggs that will give rise to females and those that will give rise to males. So, the sex chromosomes, by virtue of the fact that they are different in the two sexes, must be responsible for the necessary difference in sex-determining genes. In organisms where the only sex chromosome present in the male is one X chromosome, it is not the presence or absence of a particular gene that is the key factor in determining the sex of the fertilized egg. The difference is in the level of the product of one or more genes that are present on the X chromosome: females with two X chromosomes have twice the number of these genes and twice the amount of gene product that is found in males with a single X chromosome and only one dose of genes. It is this difference in the amount of gene products of specific genes on the X chromosome that determines whether a fertilized egg will develop into a male or a female. Surprisingly, the difference in the level of product made by genes on the X chromosome in males and females is responsible for sex determination even in some organisms where the males have both an X and a Y chromosome.

It is generally believed that all of the sex chromosome types that are found in modern species were derived from the more primitive situation of sex determination by a simple difference in the alleles of a gene present on a pair of identical chromosomes. In most diplodiploid species, one member of the sex chromosome pair is very different from the other, in shape and with respect to the genes that it carries. The changes that, over evolutionary time, eventually result in different sex chromosomes can be limited to a small segment of the chromosome or they can affect the entire chromosome. Ever since the discovery of sex chromosomes and their correlation with sex determination, the causes of these changes have been the object of considerable speculation (see, e.g., Traut and Marec, 1996; Charlesworth, 2002). Although they perform an essential genetic function, sex chromosomes also present a very serious problem to the species where they are found. It is appropriate for the Y or W chromosomes to contain genetic information that is present nowhere else in the genome and that determines that a fertilized egg will develop into an adult of a particular sex. It is also appropriate for the X (or Z) chromosome to contain sex-determining genes leading to different levels of products in XX and XY or X individuals or in ZZ or WZ individuals. But many of the numerous genes present on the pair of ancestral sex chromosomes that had nothing to do with sex determination are still located on the modern X or Z; therefore, these genes are present in two doses in XX or ZZ embryos and in a single dose in X, XY, or WZ embryos. Since the products of these genes are equally important to the development and well-being of both sexes, a difference in their level in XX and X or XY (or ZZ and WZ) individuals could lead to an imbalance in the level of gene products between sex-linked and autosomal genes whose relative contributions to particular developmental or metabolic pathways would be different in males and females. This, in turn, could result in differential selection between the sexes. As it happens, a number of insect species have avoided this problem through the evolution of a special regulatory mechanism called "dosage compensation" that renders the level of most of these gene products equal in the two sexes.

1.7.2. Dosage Compensation in *Drosophila*

1.7.2.1. Historical Perspective

The phenomenon of dosage compensation was discovered in *Drosophila melanogaster* by Herman J. Muller. His seminal observation, first reported in 1932 and later fleshed out in his famous Harvey Lecture of 1950, consisted of a comparison of eye pigment levels in males and females that carried various doses of an X-linked hypomorphic mutation (Muller, 1950). Muller noted that, although the level of pigmentation was proportional to the dosage of the hypomorphic alleles in each sex, males with one dose and females with two doses had exactly the same level of pigment (**Figure 1**). He concluded that there must exist a regulatory mechanism that compensates for the difference in dosage of X-linked genes between males and females; although he had discovered it using a mutant allele, he perceived that this regulation must surely apply to all or most wild-type genes present on the X chromosome.

Some 25 years after Muller's discovery, the famous evolutionist Theodosius Dobzhansky noted that the polytenic X chromosome in salivary glands of male larvae is wider and more diffuse than each X chromosome in the glands of females (Dobzhansky, 1957). The significance of this observation was provided by George Rudkin (Rudkin, 1964) who determined that the DNA content of the male X is equal to that of each X in females, leading to the hypothesis that the difference in morphology of this chromosome in the two sexes reflects a difference in levels of activity. This hypothesis was substantiated by A.S. Mukherjee in Wolfgang Beermann's laboratory using what, at the time, was a state-of-the-art molecular technique: transcription autoradiography (Mukherjee and Beermann, 1965). This technique

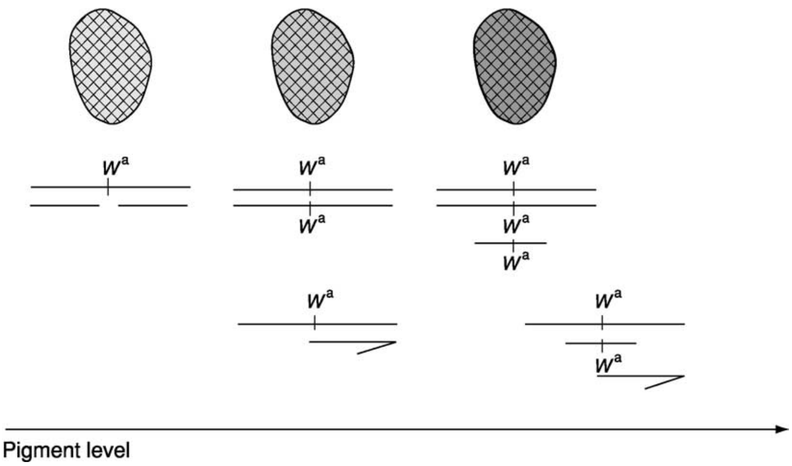

Figure 1 Phenotypic response to different genomic doses of the eye-color hypomorphic mutation white-apricot (w^a) in *Drosophila*. Different levels of pigmentation are exhibited in proportion to gene dosage within each sex, but females with two doses of the gene (upper row) have identical pigment levels as males with a single dose (lower row). The extra dose of w^a is present on a small duplication. (After Muller, H.J., **1950**. Evidence of the precision of genetic adaptation. *Harvey Lect. Ser. 43*, 165–229.)

consists of placing the salivary glands of male and female larvae in a medium containing the labeled RNA precursor [^{3}H]-uridine for a few minutes, spreading the chromosomes and covering them with a photographic film. Following a period of incubation, the film is developed and the silver grains overlying the X chromosome and an autosomal region used for control are counted. The similarity in the relative number of grains in males and females was taken as evidence that the single X chromosome in males synthesizes RNA with an efficiency similar to that of the two X chromosomes in females (Table 1).

Fifteen years later, John Belote was able to induce and recover a number of autosomal mutations that were lethal in males but had no effect on the viability of females (Belote and Lucchesi, 1980a). Using transcription autoradiography, he showed that these mutations resulted in a significant reduction in the level of transcription of the X chromosome in males (Belote and Lucchesi, 1980b). Belote's mutations could be ascribed to two separate genes – *mle* (maleless) and *msl3* (male-specific lethal on the third) – that had been discovered in natural populations by Japanese investigators (Fukunaga *et al.*, 1975; Uchida *et al.*, 1981), and to two novel genes that he named *msl1* and *msl2* (male-specific lethal one and two, respectively). Belote's work not only resulted in the identification of four different gene products involved in the execution of dosage compensation but also in the demonstration that dosage compensation in *Drosophila* is achieved by enhancing the transcription of X-linked genes in males rather than by reducing the transcription of these genes in females. All of these results

Table 1 RNA synthesis along the X chromosome in males and females

Nuclei[a]	*X autosomal segment 1*[b]	*X autosomal segment 2*
Female	8.78	1.94
Male	9.15	1.98
Female	9.29	1.85
Male	9.55	1.75

[a]Two sets of results are presented: in the top set, nuclei with high levels of labeling were selected and used for determining the average grain count on the X chromosome relative to the autosomal fragments; in the bottom set, the same calculation was performed with nuclei with low levels of labeling. No significant differences can be seen between the two types of nuclei.
[b]Autosomal segments 1 and 2 are two different regions of chromosome 3L; the level of RNA synthesis by these autosomal regions is expected to be similar in males and females.
Adapted from Mukherjee, A.S., Beermann, W., **1965**. Synthesis of ribonucleic acid by the X-chromosomes of *Drosophila melanogaster* and the problem of dosage compensation. *Nature 207*, 785–786.

emphasized a remarkable aspect of the mechanism that had been inferred since Muller's original observation: dosage compensation consists of a fairly precise twofold enhancement in gene expression.

The next landmark in the study of compensation was contributed by Thomas Skripsky (Lucchesi and Skripsky, 1981) who used the phenotypic effect of mutant interactions to discover a direct relationship between *Sxl* (Sex lethal), the master regulatory gene of female differentiation (Cline, 1979) (see also **Chapter 1.1**), and the absence of dosage compensation in females. In 1991 the first of the dosage

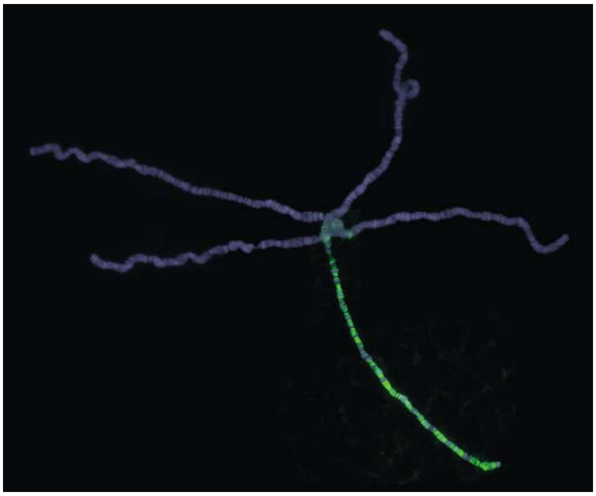

Figure 2 Polytene chromosomes from a salivary gland of a male *Drosophila* third instar larva. The chromosomes were exposed to a mouse antiserum against MSL3, then to a goat fluorescein isothyocyanate (FITC)-labeled antiserum against mouse immunoglobulin. Following immunostaining, the chromosomes were counterstained with 4,6-diamino-2-phenoleindole (DAPI). MSL3 (green fluorescence) is present at hundreds of sites along the X chromosome and is absent from the autosomes (blue fluorescence). (From a preparation made by Dr G.L. Sass in the author's laboratory.)

compensation genes (*mle*) was cloned by Mitzi Kuroda who showed by cytoimmunofluorescence that its product, as expected, "painted" the X chromosome in males (Kuroda *et al.*, 1991). Since that time, all of the known factors responsible for dosage compensation have been shown to have the same cytological distribution (**Figure 2**).

1.7.2.2. Recent Molecular Studies

Today, we have learned a great deal about the molecular basis of the mechanism of dosage compensation in *Drosophila*. The enhancement of transcription in *D. melanogaster* and, most probably, in other members of the genus is the responsibility of a multiprotein complex that represents a unique example of a novel type of chromatin remodeling machines. It is important at this point to remember that DNA does not occur in free form in the nuclei of eukaryotic cells; rather it is wrapped around octets of histones – the nucleosomes – and organized into a coiled chromatin fiber that is unfavorable to gene expression. Almost invariably, in order to allow transcription to initiate and proceed, the association of DNA with nucleosomes must be modified. This is achieved by the action of multiprotein complexes that use the energy liberated by the hydrolysis of ATP to reposition nucleosomes along the DNA, thereby allowing the transcription machinery to access more easily promoters and their regulatory

Table 2 Components of the MSL (male specific lethal) complex

Constituents	*Location*	*Features*
Proteins		
MSL1	Chromosome 2	Contains an acidic-rich region and a coiled-coil domain
MSL2	Chromosome 2	Contains a ring finger and a Mtn-like domain (synthesis repressed by the sex-lethal protein)
MSL3	Chromosome 3	Contains two noncanonical chromodomains
MLE	Chromosome 2	Member of the DEAD/H RNA helicase family
MOF	X chromosome	Histone acetyltransferase; member of the chromo-MYST family
RNAs		
roX1	X chromosome	Nuclear noncoding RNA, 4.1 kb
roX2	X chromosome	Nuclear noncoding RNA, 0.6 kb

DEAD/H, Asp-Glu-Ala-Asp (or His) box, one of eight conserved sequence motifs in RNA helicases; MYST, MOZ implicated in acute myeloid leukemia, YBF2/SAS 3 and SAS 2 involved in transcriptional silencing in yeast, and Tip60 involved in HIV Tat interactions.

sequences. It can also be achieved by the action of complexes that covalently modify histone tails and alter their affinity for DNA by targeting specific enzymes such as histone acetyltransferases or methyltransferases (reviews: Becker and Horz, 2002; Peterson, 2002).

The complex responsible for dosage compensation in *D. melanogaster* consists of at least five proteins (**Table 2**). It is referred to as the MSL complex because of the male-specific lethality of loss-of-function mutations of its protein components; similar complexes are most likely to exist for the same purpose in other members of the genus (Bone and Kuroda, 1996; Marin *et al.*, 1996; Steinemann *et al.*, 1996). In *D. melanogaster*, the complex includes both a histone acetyltransferase, males absent on the first (MOF) (Hilfiker *et al.*, 1997), and an ATPase, MLE, an ATP-dependent DNA/RNA helicase (Lee *et al.*, 1997). The presence of a sixth protein – a tandem kinase (JIL1) – has been deduced because it is enriched on the X chromosome in salivary glands of male larvae (Jin *et al.*, 1999, 2000) but it is not clear at this time whether JIL1 is an integral subunit of the complex or whether its presence is enhanced on the X chromosome in males because it is involved in the process of transcription and the relative level of transcription of the X chromosome is greater due to the process of compensation.

The MSL complex also contains at least one of the two noncoding RNAs, roX1 and roX2 (RNA on the X one and two, respectively). The existence of these RNAs was first reported independently by Victoria Meller and by Hubert Amreim (Amrein and Axel, 1997; Meller *et al.,* 1997). Both investigators had been searching for male-specific transcripts in the mushroom bodies of *Drosophila* in order to better understand sexual behavior; the roX RNAs were not only present in the brains but also in other somatic tissues of males and their distribution on polytene chromosomes of salivary glands of male larvae was limited to the X, closely following that of the MSL complex. Under normal circumstances, the roX RNAs are essential for the assembly of the complex and they are rapidly degraded if they do not associate with some of the proteins of the MSL complex (Meller *et al.,* 2000). Surprisingly, although they are completely different in size and sequence (**Table 2**), the two RNAs can substitute for each other in that males that can transcribe only one of them compensate normally and are fully viable (Meller and Rattner, 2002).

The complex is absent in females because in this sex, *Sxl* prevents its formation by inhibiting the translation of the *msl2* message (Bashaw and Baker, 1997; Kelley *et al.,* 1997; also see **Chapter 1.1**); the absence of MSL2, in turn, leads to a significant reduction in the level of MSL1 and, without these components, the complex does not form. Formation of the complex can be forced in females by the expression of a *msl2* transgene modified to allow translation of its message; in such females, the complex accesses both X chromosomes, enhances the transcription of most X-linked genes creating an imbalance with autosomal gene products and a drastic reduction in viability. It should be noted that the Y chromosome plays no role in the presence of the complex in males. This is evidenced by the observations that males lacking a Y chromosome and XXY females are fully viable; the former have normal dosage compensation while the latter do not.

In males, the complex associates exclusively with the X chromosome at hundreds of sites and its presence is correlated with the presence of a specific isoform of histone H4, monoacetylated at lysine 16. This was first observed by Bryan Turner (Bone *et al.,* 1994) who noted that this isoform is found only on the X chromosome in males. Using antisera against MSL1 or HA-tagged MSL2 (HA is a polypeptide sequence from the influenza A virus haemagglutinin) to purify the MSL complex from S2 cells, a commonly used cell culture line, Edwin Smith and Antonio Pannuti showed that this partially purified complex specifically monoacetylates H4 at lysine 16 on isolated *Drosophila* nucleosomes (Smith *et al.,* 2000). They also showed that this acetylation is absent when the complex is isolated from S2 cells that express a mutant MOF protein (the histone acetyl transferase of the complex). This work showed that MOF is uniquely responsible for the presence of H4Ac16 on the male X chromosome.

What are the factors and parameters that target the MSL complex to its many sites of action on the X chromosome and exclude it, under normal circumstances, from accessing autosomal sites? Since the roX RNAs are immediately degraded unless they associate with the proteins of the complex, and are necessary for its assembly, this assembly occurs at or near the site of transcription of the *roX* genes, and these genes are on the X chromosome. If an *roX* gene is relocated to an autosomal ectopic site, the MSL complex is found at this site (Kelley *et al.,* 1999), where it enhances the transcription of a reporter gene (Henry *et al.,* 2001). Along the X chromosome there are 30–40 sites for which the complex has a particular affinity; these sites – so-called "entry sites" – are defined as points along the X chromosome where inactive (with a mutant MLE or MOF subunits) or even partial complexes (consisting only of MSL1 and MSL2 subunits) can bind (Lyman *et al.,* 1997; Demakova *et al.,* 2003). Two of these sites are associated with the two *roX* genes and a third site has been identified from the 18D10 region of the X chromosome (Kelley *et al.,* 1999; Oh *et al.,* 2004). Although clearly special in nature, these sites are probably not exclusively responsible for the spreading of the complex along the X chromosomes.

In order to spread along the remainder of the X chromosome, the complex needs both ATPase/helicase and histone acetyltransferase activities; complexes with full-length but inactive enzymatic subunits access only the entry sites and are found, unbound, in the nucleoplasm (Gu *et al.,* 2000). In wild-type males, the distribution of the complex along the X chromosome in salivary glands of male larvae is not uniform and there are regions where its presence is reduced or where it is absent altogether (**Figure 2**). The explanation for this observation was provided by Georgette Sass who demonstrated that the distribution of the complex reflects the transcriptional activity of the X chromosome in a particular tissue where the complex accesses activated genes (Sass *et al.,* 2003). In these genes, it does not specifically target the promoter; rather it acetylates H4 at lysine 16 throughout the length of transcriptional units and beyond. This was shown to be the case by Edwin Smith who used chromatin immunoprecipitation to map this acetylation on genes known to be dosage compensated (Smith *et al.,* 2001).

This and other observations have led to the working hypothesis that the role of the acetylation mediated by the MSL complex is to facilitate transcription elongation, i.e., that the primary mechanistic target of the complex is to facilitate the processivity of the activated transcription complex. Of course, in order to result in a twofold increase in the steady-state level of transcripts, enhanced elongation must be coupled with enhanced reinitiation. The presence of the MSL complex along activated loci and its proposed specific effect on the elongation phase of transcription remind us of the association of the yeast and human Elongator complexes with activated RNA polymerase II (Otero *et al.,* 1999; Hawkes *et al.,* 2002; Kim *et al.,* 2002). Although these complexes acetylate histone H3 and, to a lesser extent, histone H4, it is not clear whether these covalent modifications are responsible for their specific role in facilitating transcription or whether they are responsible for maintaining a global level of acetylation throughout activated regions of the genome (Winkler *et al.,* 2002).

Before ending this section, it should be noted that although significant progress has been achieved in dissecting the molecular mechanisms responsible for dosage compensation, no progress has been made beyond the realm of speculation in determining what limits the transcriptional enhancement to a more or less precise twofold level.

1.7.3. Dosage Compensation in Other Insects

1.7.3.1. Haplodiploid and Parthenogenetic Species

Dosage compensation is a regulatory mechanism designed to cancel the potentially negative consequences of sex chromosome heteromorphism that is characteristic of diplodiploid species (an extreme form of which is the absence, in the heterogametic sex, of a homolog of the X or Z chromosomes). The problem that such a situation presents derives from the imbalance in the level of gene products between sex-linked and autosomal genes whose relative contributions to particular developmental or metabolic pathways would be different in males and females. Such an imbalance does not exist in haploid genomes where the ratio of sex-linked to autosomal genes is the same as in diploids. Therefore, while haploidy does generate its own particular problems relating, for example, to smaller cell size, the question of dosage compensation is not relevant to paternal-genome-loss species or parthenogenetic species with the exception of those cases where the paternal genome is retained in an active form in somatic cells and is lost only during oogenesis. In such cases, given the presence of two X chromosomes in some of the embryos and of a single X in others, the possibility of a mechanism for dosage compensation exists. Unfortunately there is no information on the level of sex-linked gene activity in these forms.

1.7.3.2. Diplodiploid Species

To establish the occurrence of dosage compensation in an organism, it is customary to identify an X-linked or Z-linked gene with a quantifiable product and to determine that the level of this product is the same in males and females. As an alternative, the time-tested technique of transcription autoradiography can be used to demonstrate that the incorporation of [^{3}H]-uridine along the X or Z chromosomes is comparable in the two sexes. Using this second methodology, the existence of dosage compensation in *Rhynchosciara* and in *Sciara* (dipteran species) was established (Casartelli and Santos, 1969; da Cunha *et al.,* 1994). In *Sciara*, Lucas Sánchez and his collaborators determined that antisera against all five protein components of the *Drosophila* MSL complex failed to stain specifically the X and associated with all chromosomes in salivary glands of male larvae, in spite of the fact that the respective *Sciara* cDNAs hybridized to single bands in *Drosophila* genomic Southern blots (Ruiz *et al.,* 2000). These observations suggest that distant genera in the same order may have subsumed different, albeit functionally related, proteins during the evolution of their dosage compensation mechanism.

Due to the usual absence or paucity of genetic information no other investigations of this type appear to have been carried out on any other insects. Instead, several workers have attempted to gain some insight into the nature of the mechanism responsible for dosage compensation in particular species without first having established that equalization of gene products between the sexes does, in fact, occur. The hypothesis tested has been, invariably, that dosage compensation would occur by the somatic inactivation of one of the two X or Z chromosomes (as occurs in all mammals). The basic approach has been to determine by a variety of cytological techniques if one of the two X or Z chromosomes in the somatic cells of XX or ZZ individuals is sensitive to particular clastogenic agents such as 5-bromodeoxyuridine, which induces aberrations in heterochromatic (inactive) chromosomes or [^{3}H]-uridine, which induces aberrations predominantly in euchromatic (active) chromosomes.

An additional test has been to determine whether one of the X or Z chromosomes is late-replicating, suggesting that it may be facultatively heterochromatic and, therefore, inactive. Using these methods, one of the two X chromosomes of *Grillotalpa fossor* and of *Acheta domesticus*, two orthopteran species, were judged to be facultatively heterochromatized and, presumably, inactivated in female somatic cells (Arora and Rao, 1979; Rao and Ali, 1982).

In *Musca domestica*, another dipteran species, the situation is complicated by the fact that, although in most populations the females are XX and the males XY, there exist instances where both sexual chromosome types are present in each sex (Nöthiger and Steinmann-Zwicky, 1985; Schmidt *et al.*, 1997). In some of these exceptional populations, the locus encoding the dominant male-determining factor M, normally Y-linked, has been translocated to an autosome. In others, the master regulatory gene of female differentiation F – normally repressed by the M factor for male differentiation – is represented by a constitutive allele. If a dosage compensation mechanism similar to the one of *Drosophila* and/or *Sciara* has evolved in *Musca* to trump the problem of X-linked dosage differences in normal populations, how can this mechanism become sex-independent in the exceptional populations, in order to allow the survival of XX and XY individuals in both sexes? The answer to this riddle is, in all likelihood, that dosage compensation is not necessary, because few, if any, genes at all are present on the X chromosome.

Another complex situation appears to prevail in *Lucilia*. In the pupal trichogen cells of this dipteran species, the autosomes exhibit the banded appearance typical of *Drosophila* polytene chromosomes, while each of the two X chromosomes in females and the single X in males are diffuse, granular masses with a small, condensed region. In contrast, the Y chromosome is predominantly condensed with a small, loosely organized segment. In XXY males, a single granular X chromosome and an additional banded element are present in trichogen cells, leading to the conclusion that the formation of such an element represents a mechanism by which the extra X-linked genes can be silenced (Bedo, 1982).

Perhaps even more surprising is the conclusion that a *prima facie* case for the absence of dosage compensation can be made in major insect groups in spite of the presence of highly heteromorphic sex chromosomes. This appears to be the case in some Lepidoptera where the specific activity of the Z-linked enzyme 6-phosphogluconate dehydrogenase is twice as high in *Heliconius melpomene* and *H. erato* ZZ males than in ZW females (Johnson and Turner, 1979). More recently, Japanese investigators measured the levels of a Z chromosome-linked transcript and an unrelated muscle protein in *Bombyx* and found them to be two times higher in males than in females (Suzuki *et al.*, 1998, 1999). These observations spell out the major caveat that the presence of heteromorphic sex chromosomes does not, of itself, imply the existence of a dosage compensation mechanism. Such a mechanism may well exist in species of current interest such as *Anopheles, Aedes, Lucilia, Ceratitis,* and others, but its presence must be evidenced by molecular substantiation.

1.7.4. Envoi

In the last decade or so, molecular genetic studies of the phenomenon of dosage compensation have provided unique and amazing windows into fundamental mechanisms of transcriptional regulation in mammals, where the facultative heterochromatization of one of the two X chromosomes in females involves the spread of noncoding RNAs as a harbinger of covalent modifications of both DNA and histones (Lee, 2003). Similar studies in *Caenorhabditis elegans* have revealed that the limited downregulation of both X chromosomes in hermaphrodites involves a subset of proteins and factors that are normally engaged in chromosome condensation during cell division (Meyer, 2000). Finally, of course, in *Drosophila* the equalization of X-linked gene products in males and females relies on a complex that may be the prototype of a novel family of chromatin remodeling complexes. Therefore, there is little doubt that, given the seemingly unending variety of developmental systems found in insects, similar studies of dosage compensation in selected model species will reveal novel and unpredictable regulatory mechanisms of gene function.

1.8 Insect Homeotic Complex Genes and Development, Lessons from *Drosophila* and Beyond

L K Robertson and J W Mahaffey, North Carolina State University, Raleigh, NC, USA

1.8.1. The History and Early Genetics of the *Homeotic Complex* Genes

1.8.1.1. Introduction

The word homeotic has its origins in the Greek word *homoios*, meaning "same" or "similar." William Bateson coined the term "homeosis" in 1894 to describe a mutation that transforms one structure to the likeness of another, particularly with respect to repeated systems such as segments, petals/sepals/stamens, vertebrae, etc. In *Drosophila* genetics, the term is used to describe a mutation that causes one segment to lose its normal identity and take on the appearance of another segment. Two well-known

Figure 1 *Drosophila* homeotic transformation. *Drosophila melanogaster* hemizygous for three regulatory mutations in the *Ultrabithorax* region of the *Bithorax Complex*: *anterobithorax* (*abx*), *bithorax*^{3} (*bx*^{3}), and *postbithorax* (*pbx*). The third thoracic segment is completely transformed to a second thoracic identity. The haltere, the dorsal appendage normally present on the third thoracic segment, is transformed to a wing, and the dorsal third thoracic cuticle develops the characteristics of the second dorsal thoracic cuticle. (Reproduced with permission from E.B. Lewis.)

examples are shown in **Figures 1** and **6c**. Pictured are a loss of function *Ultrabithorax* (*Ubx*) mutant, in which the halteres (balancing organs found on the third thoracic segment) are transformed to second thoracic wings, and a gain of function *Antennapedia* (*Antp*) mutant, in which the antennae are transformed to legs.

There are many homeotic mutations scattered throughout the *Drosophila* genome, but two regions on the right arm of the third chromosome are unique. These two clusters of homeotic genes, the *Antennapedia Complex* (*ANT-C*) and the *Bithorax Complex* (*BX-C*), are referred to jointly as the *Homeotic Complex* (*HOM-C*). *HOM-C* genes direct regional specification of the anterior–posterior body axis in insects as well as in other animals (in which they are called the *HOX* genes). The organization and expression patterns of these genes are collinear; in general, a gene's domain of expression along the anterior–posterior body axis correlates with its genomic position within the complexes (**Figure 2**). This collinearity is also conserved across phyla.

1.8.1.2. Identification of the *Drosophila Bithorax* and *Antennapedia Complexes*

The first homeotic mutation identified in *Drosophila* was *bithorax*^{1} (*bx*), isolated in Thomas Hunt Morgan's laboratory in 1915 by C.B. Bridges. This mutation affects the third thoracic segment, transforming part of the haltere towards wing. Other homeotic mutations were isolated in the following years, but it was not until the work of Edward B. Lewis that the *HOM-C* was recognized as a complex of genes required for proper anterior–posterior patterning.

Lewis began his work on genes within the *BX-C* in 1946 because these genes appeared to be organized in a cluster of duplicated and diverged genes, rather than as a series of alleles of the same gene (Lewis, 1998) – the mutant loci within the cluster were functionally related and separable by recombination, while maintaining their mutant phenotypes. The isolation of a deficiency (*Df-P9*) deleting the entire *BX-C* allowed Lewis to characterize the functions of each mutation along the *BX-C* individually and together.

Lewis' seminal review article (Lewis, 1978), describes his view on the organization and developmental function of the *BX-C*. Important was his observation that individual mutations within the complex cause transformations within specific, and sometimes exclusive, body regions. For example, the *bx* mutation effects only the anterior of the third thoracic segment, while the *bithoraxoid* (*bxd*) mutation transforms the posterior portions of the third thoracic segment and the first abdominal segment towards a posterior second thoracic identity. Based on adult and larval phenotypes of *BX-C* mutations, Lewis proposed that at least eight genes existed within the complex, which "seem(s) ... to control much of the diversification of the organism's thoracic and abdominal segments." He further suggested that these genes act "indirectly by repressing or activating other sets of genes which then directly determine the specific structures and functions that characterize a given segment." Lewis also put forth the idea that such genetic changes explained evolutionary changes in body pattern – such as the change in insects from four wings, as in lepidopterans, to the two wings found in dipterans, through the development of what Lewis called "a haltere promoting gene." Similarly, Lewis suggested that the reduction in insect leg number, from an early millipede-like ancestor, might be explained by the development of a "leg-suppressing gene." Finally, Lewis also identified mutations that defined the *Polycomb* (*Pc*) gene as encoding a regulator of the *BX-C* genes. *Polycomb* is the founding member of a group of genes that are involved in maintaining proper homeotic gene expression patterns, and is further discussed below (see Section 1.8.3.2).

In 1980, using deficiencies and complementation analysis, Thomas C. Kaufman and colleagues identified a second cluster of homeotic genes on the right arm of the third chromosome (Kaufman *et al.*, 1980) (**Figure 2**). Like the *BX-C*, the genes in this cluster had the ability to cause homeotic transformations of one segment type to another, but this cluster of genes controlled the development of the head and anterior thorax, and was named the

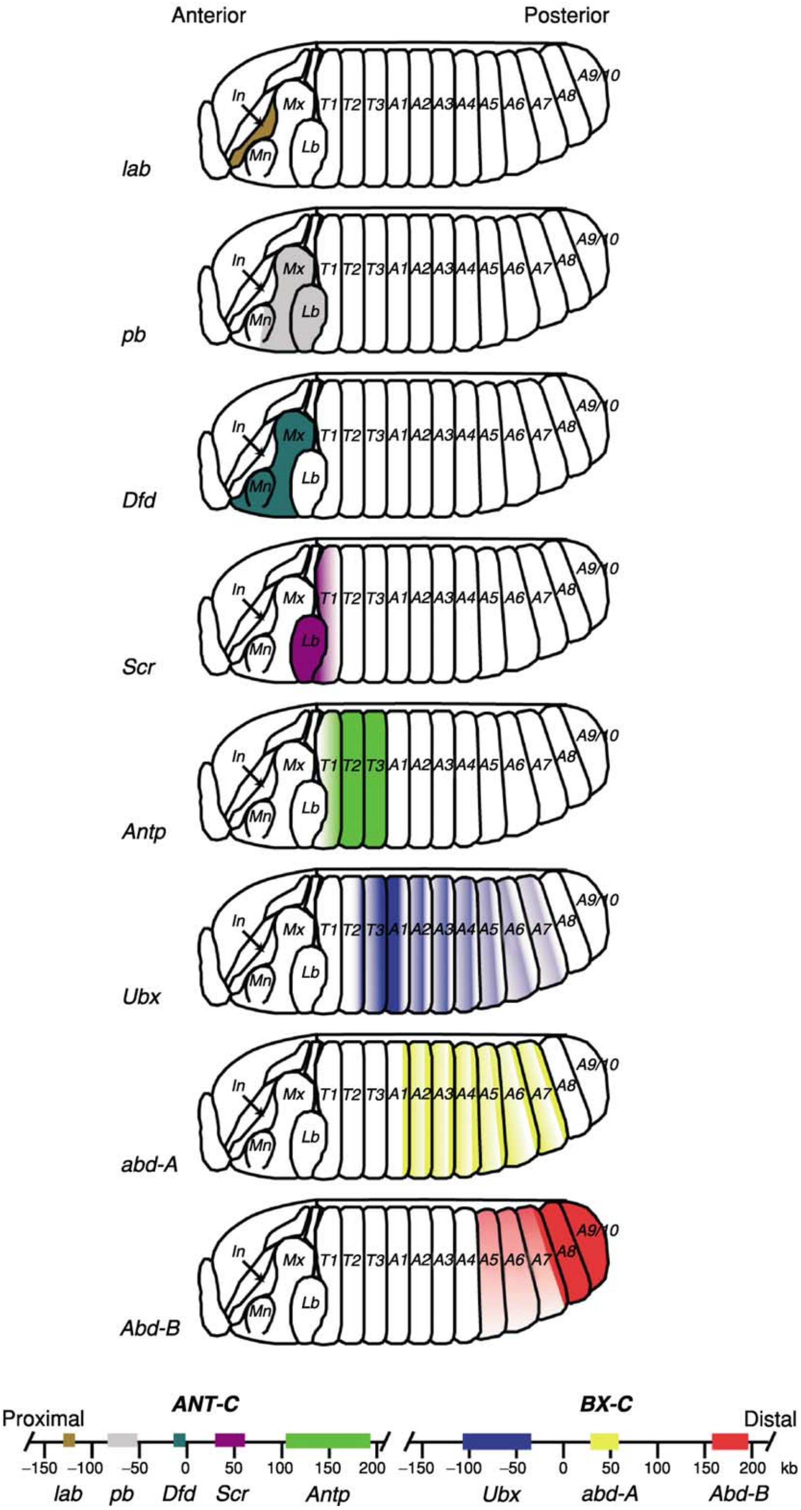

Figure 2 Regional HOM-C gene expression in *Drosophila* embryos. A simplified representation of the *HOM-C* genes' epidermal expression domains. Each gene's relative position within the *ANT-C* or *BX-C* is also shown. The collinearity of genomic location and expression along the embryonic axis is evident. The variation in the shading intensity approximates variations in the level of gene expression. Numbers along the complex are in kilobases. In, intercalary; Mn, mandibular; Mx, maxillary; Lb, labial; T#, thoracic segments; A#, abdominal segments. See text for references.

Antennapedia Complex (*ANT-C*) after its first characterized gene.

A number of diverse homeotic transformations correspond to mutations within the *ANT-C*, and many of the initially recovered mutations lead to viable, transformed adults. For example, one deficiency causes the reduction of male sex combs on the first thoracic leg, indicating that genes within this region are required for first thoracic leg identity. A gain-of-function mutation transforms the second and third thoracic legs to a first thoracic identity as evidenced by the presence of ectopic sex combs on the male second and third thoracic legs (Kaufman *et al*., 1980). Saturating X-ray and ethyl methanesulfonate (EMS) mutatagenesis allowed more precise characterization of the complex and the beginnings of the developmental mapping of the *ANT-C* genes (Lewis *et al*., 1980a, 1980b; Kaufman *et al*., 1990). The analogy to the *BX-C* suggested that larval recessive lethal mutations, resulting in homeotically altered larvae, ought to be recoverable from the *ANT-C*, and this proved to be the case (Wakimoto and Kaufman, 1981; Wakimoto *et al*., 1984; Sato *et al*., 1985).

Although genetic analyses demonstrated a requirement for the homeotic genes for the establishment of the correct body pattern of the fly, how homeotic genes accomplished this was also on the minds of these pioneering researchers. Both Lewis and García-Bellido predicted correctly that the homeotic genes encoded proteins that controlled the expression of other genes (García-Bellido, 1977; Lewis, 1978). García-Bellido referred to the homeotic genes as "selector" genes that encoded developmental switches sending the expressing cells down one or another developmental pathway. He proposed that "realizator" genes were the receivers of this message and that these encoded the products constructing specific segmental identities.

1.8.1.3. Cloning and Characterization of the *Antennapedia* and *Bithorax Complexes*

The *BX-C* and *ANT-C* regions were cloned at about the same time in different laboratories. The Hogness laboratory initiated a chromosome walk in the *Ultrabithorax* (*Ubx*) region and cloned the *BX-C* in 1983 (Bender *et al*., 1983). Both Kaufman's group and Walter Gehring's laboratory cloned the *ANT-C* complex, also in 1983 (Scott *et al*., 1983; Garber *et al*., 1983). The next significant discovery, in 1984, was that of the homeobox. This 180 bp sequence was found to be present in all *HOM-C* genes (McGinnis *et al*., 1984; Scott *et al*., 1985) and supported Lewis's original idea that the *BX-C* might represent a group of duplicated and diverged genes. The *ANT-C* was found to contain one homeobox for each homeotic gene that was characterized, and for a few that were not located within homeotic loci. The *BX-C* was, however, found to have only three homeobox sequences – significantly fewer than the eight genes predicted to reside in this region (Regulski *et al*., 1985). This discovery, along with further genetic analysis demonstrating the existence of only three lethal complementation groups in the *BX-C*, confirmed that only three genes reside within this region (Sánchez-Herrero *et al*., 1985). The remaining "genes" proved to be *cis*-regulatory elements that control subdomains of *BX-C* gene expression (see Section 1.8.3.3).

One major difference between the *ANT-C* and the *BX-C* is the presence of intervening, nonhomeotic genes within the *ANT-C* (**Figure 3**). The *fushi tarazu* (*ftz*), *bicoid* (*bcd*), *zerknüllt* (*zen*), and *zerknüllt-2* (*z-2*) genes are all required during early embryogenesis, and all of these genes contain a homeobox. Interestingly, *bicoid*, *zerknüllt*, and *zerknüllt-2* are thought to have arisen through the duplication and divergence of a single ancestral *HOM-C* gene (Falciani *et al*., 1996; Stauber *et al*., 1999). Also present in the *ANT-C* is a cluster of cuticle synthesis genes, which are repeated elsewhere in the genome and do not appear to be required for development. Finally, *amalgam* (*ama*), encoding a protein involved in cell adhesion, is also present in the *ANT-C*.

In the years following, a vast amount of study has examined *HOM-C* gene function, regulation, and structure in detail. The complexes are conserved in virtually all animals, as are the axial patterning functions and collinear relationship between expression patterns and genomic arrangement. Studies have further characterized mutant phenotypes, expression, function, and the genomic structure of the *HOM-C* genes in *Drosophila* and other insects. In 1995, Edward Lewis, along with Eric Wieschaus and Christiane Nüsslein-Volhard, were awarded the Nobel Prize for Physiology or Medicine for their discoveries concerning the genetic control of early embryonic development. We will, in subsequent pages, attempt to present a comprehensive summary of *HOM-C* gene study in insects and will add results from other organisms where appropriate.

1.8.2. *HOM-C* Gene Function, Cytology, Expression, and Mutant Phenotypes

1.8.2.1. Introduction

Without doubt, *Drosophila melanogaster* is the most studied organism with regard to the *HOM-C* genes. These transcription factors were initially identified

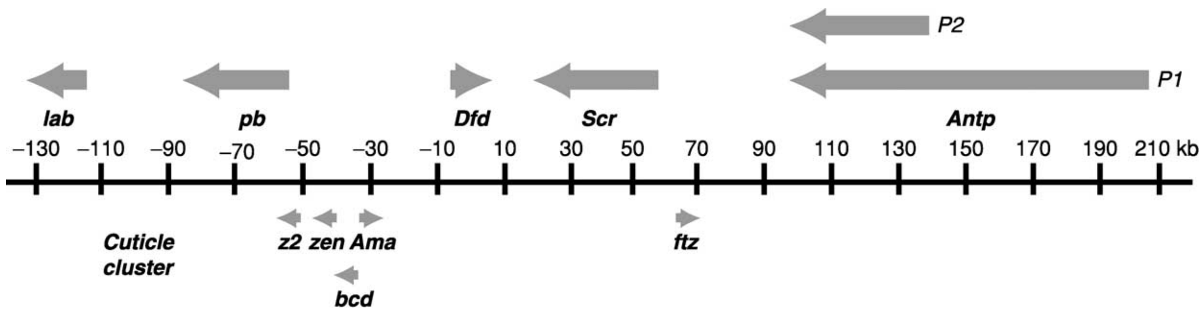

Figure 3 The molecular organization of the *Drosophila Antennapedia Complex* (*ANT-C*) locus. This portion of the *Drosophila melanogaster Homeotic Complex* (*HOM-C*) differs from the *Bithorax Complex* (*BX-C*) region by the presence of a number of genes not considered to have homeotic function, *per se*. A cluster of 16 cuticle genes lies between the *labial* (*lab*) and *proboscipedia* (*pb*) loci. The region between *pb* and *Deformed* (*Dfd*) is intervened by *zen 2* (*z2*), *zen* (*zen*), *bicoid* (*bcd*), and *amalgam* (*ama*). Finally, *fushi tarazu* (*ftz*), lies within the *Sex combs reduced* (*Scr*) regulatory region. The horizontal line represents approximately 340 kb of the *ANT-C* region marked in kilobases. The divisions derive from the extension of a chromosomal walk initiated by Scott *et al.* (1983) with the *Dfd* locus at the zero point. Arrows above and below the horizontal lines designate the genomic regions contributing to each gene's transcript(s) and the relative direction of transcription. The regions under the control of the P1 and P2 promoters of *Antennapedia* (*Antp*) are indicated separately.

and characterized in the fruit fly, and much of what is known of their regulation and function has come from this work. Characterization of *HOM-C* gene expression, function, and molecular organization also extends to a number of other animals, including nondrosophilid insect species and noninsect arthropods. Better-characterized insects include the apterygote insect *Thermobia domestica* (firebrat), *Schistocerca americana* (grasshopper), *Oncopeltus fasciatus* (milkweed bug), *Tribolium castaneum* (red flour beetle), *Bombyx mori* (silk moth), *Precis coenia* (butterfly), and *Apis mellifera* (honey bee). Less studied insects include *Ctenocephalides felis* (flea), *Aedes albopictus* and *Anopheles gambiae* (two mosquito species), *Schistocerca gregaria* (locust), *Acheta domesticus* (cricket), *Folsomia candida* (basal terrestrial apterygote), and *Neodiprion abietis* (sawfly).

In most animal species other than *Drosophila*, the *HOM-C* genes are clustered together in a single complex, differing from the split complexes observed in several *Drosophila* species (Beeman, 1987; Ferrier and Akam, 1996; Davenport *et al.*, 2000; Powers *et al.*, 2000; Cook, 2001). This split appears to have occurred within the *Drosophila* lineage, as different *Drosophila* species have split the complex in different locations (Von Allmen *et al.*, 1996; Negre *et al.*, 2003). This implies that the *Drosophila* ancestor likely had a single complex and the single insect *HOM-C* is the ancestral state. The size of the characterized clusters varies among insect species. For example, the portion of the *Tribolium* complex corresponding to the *Drosophila ANT-C* is approximately 279 kb, while the same region in *Drosophila* includes approximately 439 kb (Brown *et al.*, 2002a).

The *HOM-C* genes of the *Drosophila ANT-C* are *labial* (*lab*), *proboscipedia* (*pb*), *Deformed* (*Dfd*), *Sex combs reduced* (*Scr*), and *Antennapedia* (*Antp*). The *HOM-C* genes of the *Drosophila BX-C* are *Ultrabithorax* (*Ubx*), *abdominal-A* (*abd-A*), and *Abdominal-B* (*Abd-B*). Each *HOM-C* gene is expressed in a regional manner, and **Figure 2** illustrates the generalized expression patterns of the *HOM-C* genes in a mid-staged *Drosophila* embryo. The maximum morphological and molecular similarity between insects is observed during the embryonic germ band stage, which may represent an evolutionarily constrained (phylotypic) developmental stage (Patel, 1994).

The characterization of each *HOM-C* gene in *D. melanogaster* is first reviewed in detail, followed by a discussion of studies in other insects with emphasis on their differences from flies. We will begin with the gene governing the anteriormost development and then move posteriorly, demonstrating the collinearity of gene order and anterior–posterior body axis.

Though often depicted with rather simple expression patterns, the *HOM-C* genes can be quite dynamic, varying in both the level and the extent of expression within each respective domain. Expression boundaries can be segmental, parasegmental, or a combination of the two, and, in some cases, the expression boundaries do not coincide with segmental or parasegmental boundaries.

Each segment can be thought of as being composed of an anterior and a posterior compartment (**Figure 4**). A parasegment has the same width as a segment, but the anterior of a parasegment is the posterior compartment of a segment, and the

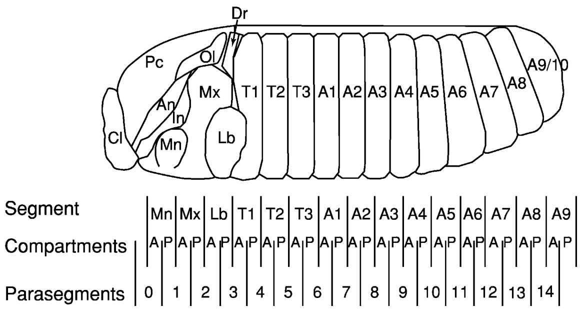

Figure 4 Segments, parasegments, and compartments. Gene expression boundaries in the developing *Drosophila* embryo can be described as segmental, parasegmental, a combination of the two, or sometimes expression boundaries coincide with neither. Parasegment (0–14) and segment boundaries are shown in relation to one another and to a germ band contracted *Drosophila* embryo. The anterior (A) and posterior (P) compartments of each segment are indicated. Parasegment boundaries are shifted anteriorly one compartment from the segmental boundaries. The anteriormost head segments are not labeled in this diagram. Cl, clypeolabrum; Ol, optic lobe; Dr, dorsal ridge; An, antennal; In, intercalary; Mn, mandibular; Mx, maxillary; Lb, labial; T#, thoracic segments; A#, abdominal segments.

posterior portion of a parasegment is the anterior compartment of the following segment. Therefore, a parasegment is similar to a segment, but it is shifted in register by one segmental compartment (Martinez-Arias and Lawrence, 1985).

The distinction between segments and parasegments is important with regard to *HOM-C* expression in the visceral mesoderm and the central nervous system (CNS). In the visceral mesoderm, the expression of most *HOM-C* genes is shifted posteriorly approximately the width of one parasegment, as compared to the ectoderm. The domains of *HOM-C* gene expression can overlap in the ectoderm, but their expression domains in the visceral mesoderm are mutually exclusive (Tremml and Bienz, 1989). As noted in the discussion below, *HOM-C* gene expression within the CNS is also frequently shifted, although by only half of a segment, such that the expression boundaries are parasegmental. The *Dfd* gene is an exception, with its expression boundaries shifting anteriorly in both the visceral mesoderm and the CNS.

1.8.2.2. The *HOM-C* Genes of the *ANT-C*

The genes of the *Drosophila ANT-C* (Figures 2 and 3) are expressed primarily in the head and thorax of the developing embryo and effect the development of corresponding regions in the adult.

1.8.2.2.1. *labial* (*lab*) As the most anteriorly expressed and most proximal (with regards to its chromosomal position) member of the *ANT-C*, *lab* is required for proper development of the intercalary head segment (Mlodzik *et al.*, 1988; Diederich *et al.*, 1989). *lab* is also required for cell fate specification in the tritocerebral neuromere (Hirth *et al.*, 1998) and for copper cell differentiation in the gut endothelium (Hoppler and Bienz, 1995). The *lab* gene spans approximately 17 kb and contains three exons, with the homeobox divided between the second and third exon. The *lab* transcript is ~3.0 kb and encodes a 67.5 kDa protein of 629 amino acids.

Transcripts of *lab* are first detected at 2 h after egg laying (AEL), with the peak of embryonic expression occurring at 6–8 h AEL (Merrill *et al.*, 1989). Expression remains constant through 16–20 h AEL, but decreases before hatching. A low level of expression can be detected throughout pupal development, and no expression is detectable in adult flies.

Temperature sensitive mutants were used to ascertain the temporal requirement for *lab* expression. These experiments have shown that the requirement for *lab* extends from 3–4 h to 16–18 h of embryogenesis, with the period from 6 to 14 h being the most critical for viability to the adult stage.

The distribution of the Lab protein has been examined in embryos and in larval imaginal discs (Diederich *et al.*, 1989; Mahaffey *et al.*, 1989). In the embryo, Lab initially accumulates during germ band extension, with two regions of expression observed. An anterior, ectodermal stripe of expression is present along the ventrolateral border of the procephalon, extending to the anterior border of the postoral segments. This region corresponds to the intercalary segment, which contains the stomadium. A more posterior domain of expression is found in the midgut, where the anterior and posterior midgut primordia fuse. Despite the gene's name, there is no detectable accumulation of Lab in the gnathal lobes (mandibular, maxillary, labial), but expression is evident in the dorsal ridge and in the CNS in the supra/subesophageal ganglia at the base of both brain hemispheres. Lab protein also accumulates lateral to the ventral nerve cord (VNC) and in individual epidermal cells that are precursors to certain sensory organs. These include cells that correspond to the labral sense organ, the black dot organs, and the sense organs of the larval tail. The Lab protein also accumulates in the eye–antennal disc in third instar larvae.

Like other homeotic genes that specify head segment identities, *lab* mutants have no obvious homeosis in the larval head. Embryos homozygous for null mutations in *lab* have grossly disrupted mouthparts and die before hatching, after failing to undergo proper head involution (Merrill *et al.*, 1989). The mandibular and maxillary lobes, which

normally fuse, fail to do so (see **Figure 5** for a diagram of the *Drosophila* larval head structures). Further, the dorsal pouch, which gives rise to the dorsal portion of the larval head, develops abnormally. This disruption of head involution leaves the clypeolabrum, maxillary and mandibular lobes, and pharynx protruding from the anterior of the embryo, so that the larval cephalopharyngeal structures are not assembled properly. The lateral processes, the H-piece bridge, and the ventral arms of the cephalopharyngeal skeleton are absent. The median tooth is broadened, and amorphous sclerotized material is present in the head. In severe mutants, the T-ribs and pharynx are affected.

Interestingly, many of the affected tissues do not express *labial* during embryonic development, and thus may suffer effects secondary to *labial* loss. Also characteristic of *lab* mutants is the appearance of sclerotized material between the anal pads in the tail region. Despite the expression of *lab* in the midgut and peripheral nervous system during larval development, these tissues appear to develop normally in the absence of *lab* (Merrill *et al*., 1989).

Analysis of adult phenotypes demonstrates the homeotic nature of *lab* mutants (Merrill *et al*., 1989). Though there are variable effects on the head (one or both of the maxillary palps are missing, the ventral margin of the eye is disrupted, and lumps of tissue with bristles protrude from the surrounding cuticle), the homeosis is obvious because thoracic-like bristles appear in posterior regions of the head, and a thoracic spiracle develops near the center of the postgena. (Labeled diagrams of the adult *Drosophila* head are available at http://www.flybase.org/anatomy/image-browser.html)

The expression of *lab* has been also examined in *Thermobia* and *Tribolium*. While expression in the intercalary segment mirrors that of the fly, *lab* is not detected in the midgut or dorsal ridge of the basal insect *Thermobia* (Peterson *et al*., 1999; Nie *et al*., 2001). Unfortunately, it is not clear whether this is due to differences in expression or to technical difficulties in the mRNA localization at later stages of development. Further, the exact role of *lab* in the intercalary segment is not well defined, as there are no common appendages arising from the intercalary segment, and it is only in the higher dipterans that *lab* would have a role in head involution (Hughes and Kaufman, 2002).

1.8.2.2.2. *proboscipedia* (*pb*) The *pb* gene is required for proper development of the adult maxillary and labial appendages but, interestingly, has no role in the development of the larva, even though it is expressed in the embryonic maxillary and labial segments (Pultz *et al*., 1988). Perhaps this is reflection of a more ancient role, where appendages are found in the maxillary and labial segments of the larva, or perhaps this expression is necessary to prepare the tissues for the adult developmental program. The *pb* gene is approximately 34 kb and contains nine exons. Alternative splicing yields four different *pb* mRNA forms, each differing immediately upstream of the homeobox and encoding a different protein isoform (Cribbs *et al*., 1992). Like *lab* and *Abd-B*, the homeobox of *pb* is split between two exons, a characteristic also observed in homologs of these genes in other animals.

Embryonic expression is first evident when the germ band is extended, immediately prior to segmentation, 5.5–6 h AEL. The Pb protein is first detected in the presumptive mesoderm behind the stomodeum. As the germ band contracts, Pb protein is detected under the mandibular lobe and in the ectoderm of the maxillary and labial lobes, gradually increasing as the gnathal lobes develop. Protein

accumulation is later evident in the ventral mandibular segment, though not in the ventral regions of the maxillary or labial segments. It overlaps partially with Dfd and Scr in these regions (Mahaffey *et al*., 1989). Pb accumulates within several cells of each neuromere in the CNS (Pultz *et al*., 1988; Mahaffey *et al*., 1989). Expression of *pb* is also evident during the late larval and pupal stages in the labial disc and a small region of the eye–antennal disc.

In complete loss of function *pb* mutants, there is no observed embryonic phenotype, which makes *pb* unique among the *ANT-C* genes of *Drosophila*. Its function is required only for proper development of the adult labial and maxillary structures (Bridges and Dobzhansky, 1933; Pultz *et al*., 1988). In strong loss-of-function alleles, the adult labial palps are transformed toward prothoracic legs, though weaker alleles transform the labial palps towards antennae. The fate of the maxillary palps in *pb* mutants is unclear; they are reduced and may be transformed toward antennae (Villee, 1944; Pultz *et al*., 1988).

The expression of the *pb* gene has been characterized in several other insects, and its function in milkweed bugs and beetles has been studied using RNA interference (RNAi) and traditional genetics, respectively. In general, the expression of *pb* is similar to that of the fly, but there is a potentially significant difference in *Oncopeltus* (Rogers and Kaufman, 1997; Rogers *et al*., 2002). Here, there is no expression of *pb* in the limb buds of the maxillary segment, but *pb* is expressed in the primordia of the maxillary plate and in the labial appendage. Rogers *et al*. (2002) suggest that this difference in *pb* expression may be correlated with, or even be the cause of, a change in the mouthpart structures from a mandibulate precursor to a stylate–haustellate type. They suggest that a change in *HOM-C* expression may cause a homeotic alteration of the maxillary appendage away from an appendage similar to that of the labial segment. If true, this would be quite interesting, as it would demonstrate that body plans could tolerate changes in *HOM-C* gene expression to yield differing developmental outcomes. RNAi reduction of *Oncopeltus pb* transforms the distal labium to first thoracic legs, similar to what occurs in the fly.

Unlike *Drosophila*, mutations in *maxillopedia* (*mxp*) (the *Tribolium* homolog of *pb*) have an embryonic effect (Beeman *et al*., 1989; Shippy *et al*., 2000). Null alleles are recessive larval lethals and cause the transformation of maxillary and labial palps toward legs. Only the distal portion of the each palp (telopodite) is transformed to leg. The proximal portion of the appendage (the coxopodite and a ventral projection called the endite lobe) remains untransformed. Normally, the labial coxopodites fuse at the ventral midline; *mxp* mutants retain the fused coxopodites, but the telopodites are transformed to legs. The degree of transformation is variable – the homeotic legs may be warped, shortened, or may resemble normal palps with only a tarsal-like claw.

RNAi has been used to investigate the role of several *Tribolium HOM-C* genes, and with *mxp*, RNAi generates phenotypes similar to null larvae. Dominant gain-of-function *mxp* mutations also exist in *Tribolium*, with phenotypes that are interpreted to be a transformation of the legs and antennae toward maxillary or labial palps. In addition, the mutant larvae have altered head capsules. Thus, the phenotype of *mxp* mutants supports the theory that an ancestral *pb*-like *HOM-C/HOX* gene had embryonic functions, which were later lost in *Drosophila*. Similar phenotypic effects are observed in *A. albopictus pb*-like mutants (Quinn and Craig, 1971), but the mutation has not been localized to the mosquito *pb* locus.

1.8.2.2.3. *Deformed* (*Dfd*) *Deformed* gene expression is required for proper development of the *Drosophila* mandibular and maxillary segments (Wakimoto and Kaufman, 1984), as well as proper cell fate specification within the embryonic brain (Hirth *et al*., 2001). The first allele was recovered in 1923 as a homozygous viable, dominant mutation reducing the anterior and ventral eye margins, and also disrupting the vibrissae (head bristles on the lower sides of the adult head capsule near the mouthparts). Later work by Wakimoto and Kaufman (1984) identified the requirement for *Dfd* in the specification of the embryonic head. The *Dfd* gene encompasses about 11 kb, having five exons, which produce a single transcript of 2.8 kb and a protein of 586 amino acids (Regulski *et al*., 1987).

Deformed is the first *HOM-C* gene to be expressed, with its protein first detectable at the cellular blastoderm stage (Mahaffey *et al*., 1989). Expression continues throughout the embryonic, larval, and pupal stages of development and is also detected in adult flies. Early embryonic expression of *Dfd* encircles the embryo, encompassing the cephalic furrow. Later accumulation is detected, transiently, in the primordia of the hypopharyngial lobes, and in the developing mandibular and maxillary segments. Expression in the CNS and mesoderm is offset anteriorly, so that mesodermal and neural expression is parasegmental. Deformed (Dfd) protein expression is also present in cells between

the developing dorsal ridge and the optic lobe. By late germ band contraction, Dfd is strongly expressed in cells within the frontal sac that will contribute to the larval eye–antennal discs. Larval expression is localized to the eye–antennal disc in the peripodial membrane and the regions destined to become the maxillary palps. The Dfd protein is also detected in the basalmost portion of the labial discs (Martinez-Arias *et al*., 1987; Diederich *et al*., 1991).

Deformed gene activity is required at two critical developmental stages: from 3 to 10 h of embryonic development and later, during larval–pupal development (Merrill *et al*., 1987). Like the other head *HOM-C* genes, *Dfd* mutants exhibit no obvious larval homeotic transformations. Null mutations in *Dfd* disrupt larval head development, causing defects in the cephalopharyngeal skeleton and in sensory structures deriving from the maxillary and mandibular segments (Merrill *et al*., 1987; Regulski *et al*., 1987). The mandibular and maxillary lobes fail to fuse and fail to internalize during head involution (a movie depicting *Drosophila* head involution is available at http://flybase.bio.indiana.edu/images/lk/Animation). Lost or reduced cephalopharyngeal structures include the mouth hooks, H-piece, maxillary cirri, maxillary sense organs, and portions of the antennal–maxillary sensory complex. In the adult, lack of Dfd causes head defects, including disruption of the dorsal and ventral postorbital bristles, changes in morphology of the postgena (including ectopic bristles), loss or reduction of the maxillary palps, the inability to appropriately extend the proboscis, and inclusion of thoracic-like bristles on the posterior head, thus suggesting a transformation to a thoracic-like identity (Merrill *et al*., 1987; Regulski *et al*., 1987).

The *Dfd* gene has been cloned from, and its expression examined in, several insects. In general, expression is similar to that in flies, being present in the mandibular and maxillary segments. Loss-of-function analysis using both genetic and RNAi techniques was undertaken in *Tribolium* and *Oncopeltus*, respectively (Brown *et al*., 1999; Hughes and Kaufman, 2000). Here, a difference from *Drosophila* may occur. Loss of *Dfd* in *Tribolium* transforms the maxillary appendages to antennae and eliminates the endites from the mandibular coxopodites (Figure 6b) (Brown *et al*., 2000). In *Oncopeltus*, depletion of *Dfd* results in the transformation of both the maxillary and the mandibular segments towards antenna (Hughes and Kaufman, 2000), and it has been suggested that this may represent a "ground state" for gnathal segment identity (Stuart *et al*., 1991). The differences observed between *Drosophila Dfd* mutants and loss of *Dfd* in other insects may, however, simply reflect the fact that there are no larval appendages in *Drosophila*. Accordingly, the phenotypes of flies and other insects may still represent equivalent developmental alterations, though one must be

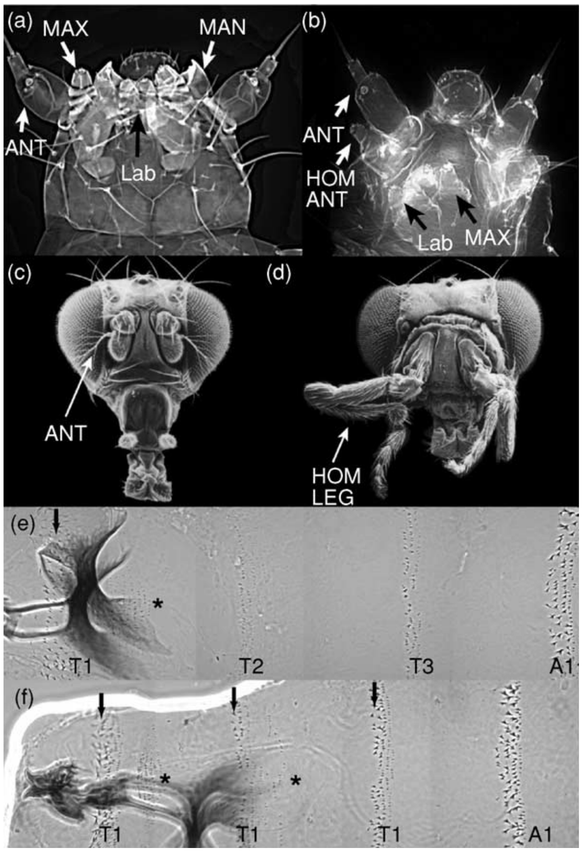

Figure 6 Phenotypic consequences of insect *HOM-C* mutations. Both loss-of-function mutations (b, f) and gain-of-function mutations (d) in the *HOM-C* genes can have dramatic phenotypic effects in *Tribolium* and *Drosophila*. Fluorescent, deconvoluted images of a wild-type (a) and a *TcDfd*[1]/*TcDfd*[1] mutant *Tribolium* larva (b). Normal antennae (ANT), mandibles (MN), maxillary palps (MAX), and labials palps (Lab) are visible in the wild-type larva. In a larva lacking *TcDfd* function (b), the mandibles are transformed to homeotic antennae (HOM ANT). A scanning electron micrograph of a wild-type (c) and a mutant (ectopic *Antp* expression) adult *Drosophila* head (d). The ectopic activation of *Antp* in the antennae (ANT) causes transformation to a second thoracic leg (HOM LEG). In a wild-type first instar *Drosophila* larva (e), the three thoracic segments differentiate characteristic denticle patterns. The first thoracic denticles include a main belt (marked with an arrow), and a second, small patch of denticles called the ''beard'' (marked by an asterisk). The morphology of the first thoracic denticles differs from those of the second and third segments, with the latter being smaller and finer. In the cuticle of an end-stage larva lacking *Antp* (f), the second and third thoracic segments are transformed towards a first thoracic identity. Note the appearance of a beard in the second thoracic denticle belt (marked by an asterisk), and the morphological change of the second and third thoracic denticles to a first thoracic type (arrows). (*Tribolium* images courtesy of S.J. Brown; *Drosophila* head images courtesy of FlyBase (FlyBase Consortium, 2003) http://www.flybase.org)

careful in interpreting any phenotype as the ground state, as it is likely that some patterning genes are still present to influence appendage development.

1.8.2.2.4. ***Sex combs reduced*** **(*Scr*)** Spanning about 100 kb, *Scr* encodes at least four separate transcripts derived from alternative splicing of four exons (Andrew, 1995). A large portion of the *Scr* regulatory region is separated from the coding region by the *ftz* segmentation gene (**Figure 3**). Mutations effecting embryonic function are 5′ to the *ftz* gene, closer to the *Scr* transcription unit, while semilethal lesions map 3′ of the *ftz* gene, towards *Antp* (Pattatucci *et al.*, 1991; Pattatucci and Kaufman, 1991). The *Scr* protein product is 417 amino acids with a molecular weight of 44 kDa (Andrew, 1995).

The *Scr* gene is particularly interesting in that it controls segment identity in two different tagma of the embryo: the labial gnathal segment and the adjoining first thoracic trunk segment. Its transcripts are first detected as gastrulation begins, 2:50 to 3:10 h AEL, and continue to be present throughout the remainder of embryogenesis (Martinez-Arias *et al.*, 1987). Although lagging by 2–3 h behind the expression of RNA, protein accumulation follows the spatial pattern of accumulation of RNA transcripts, being found throughout the labial lobes and the anterior half of the first thoracic segment (Mahaffey and Kaufman, 1987). In addition, a few cells in the dorsal ridge also accumulate the Scr protein. As the germ band begins to contract, Scr protein accumulates in the midgut visceral mesoderm (Tremml and Bienz, 1989; Reuter and Scott, 1990). The Scr protein is also required for development of the salivary glands, and accumulates in the salivary gland primordia prior to invagination. However, Scr is entirely absent after invagination of the developing glands. The *Scr* transcripts and protein accumulate in third instar larval first thoracic discs (leg and humeral) and in the labial discs (Mahaffey and Kaufman, 1987). In larvae, the Scr protein is localized to the VNC and in the majority of the labial discs, the first thoracic leg discs, and the dorsal region of the first thoracic humeral discs (Mahaffey and Kaufman, 1987; Glicksman and Brower, 1988). Protein accumulation is also weakly detectable in the second and third thoracic leg discs, but not in the dorsal counterparts of these (wing and haltere). In the adult, the protein is detected in the CNS, in the subesophageal region only.

In the embryo, the homeotic nature of *Scr* appears only in the first thoracic segment, which, in null *Scr* mutants, is transformed to a second thoracic identity. The posterior denticle belt (beard) is lost and the remaining anterior denticles assume a second thoracic morphology. Also, in embryos lacking Scr, the labial lobes fail to undergo head involution, leaving the normally internalized labial sense organs external. Although it was initially reported that the labial segment was transformed to a maxillary identity, closer examination indicated that this was not the case (Pederson *et al.*, 1996). Thus, as with other head homeotic genes, there is no larval homeotic transformation of the labial segment corresponding to the absence of Scr. Loss of *Scr* eliminates structures generated by the labial segment: the salivary glands and the bridge of the H-piece (Panzer *et al.*, 1992). Expression of *Scr* is further required in the visceral mesoderm for the formation of the gastric caeca (Reuter and Scott, 1990.). In the adult, loss of *Scr* disrupts patterning of the first thoracic discs (leg and humeral) (Pattatucci *et al.*, 1991). In the transformed first thoracic segment of adults, the leg develops with a second thoracic identity, as evidenced by the bristle pattern and the reduction of sex comb teeth in males. Occasionally, a bit of wing-like appendage appears in the dorsal first thoracic segment (Struhl, 1982; Kaufman, 1990).

Along with *pb*, *Scr* is also required for adult proboscis development (Percival-Smith *et al.*, 1997; Rogers *et al.*, 1997; Abzhanov *et al.*, 2001). In null clones of *Scr*, the labial palps transform toward a maxillary palp identity. Dominant gain-of-function mutants also exist that affect adult structures. These cause a partial transformation of the second and/or third thoracic legs toward a first thoracic identity (Pattatucci and Kaufman, 1991).

Although labial expression of *Scr* appears conserved in other insects, indicating that this gene has a conserved role in development of this segment, its expression and role in the first thoracic region is somewhat variable. In *Oncopeltus*, *Acheta*, and *Thermobia*, *Scr* expression is limited to the leg spot domains in the first thoracic segment, in contrast to its expression in the entire anterior first thoracic compartment in *Drosophila*, *Tribolium*, and *Apis* (Rogers *et al.*, 1997; Walldorf *et al.*, 2000; Curtis *et al.*, 2001). It appears, therefore, that the role of *Scr* in the first thoracic segment has expanded in higher insects.

More controversial, however, is the dorsal patch of *Scr* expression in “lower” insects. In flies, expression of *Scr* in dorsal first thoracic tissue prevents development of ectopic wing structures. This has also been proposed to be the role of the dorsal expression in *Oncopeltus* and *Acheta*. However, a similar dorsal region of expression is found in *Thermobia*, and, as a more basal apterygote, *Thermobia*

is not likely to require wing suppression (Rogers *et al*., 1997).

RNAi has been used to remove *Scr* function from *Oncopeltus*, and genetic analysis has been used to study the role of the *Scr* homolog *Cephalothorax* (*Cx*), in *Tribolium*. In *Oncopeltus*, the depletion of *Scr* results in transformation of the normally fused labium to two small leglike structures (Hughes and Kaufman, 2000). In the first thoracic leg, the bristles of the comb are altered to resemble those found on more posterior legs. In *Tribolium*, there are two classes of mutations in the *Cx* gene (Beeman *et al*., 1989; Curtis *et al*., 2001). RNAi was used to determine which is likely to be the null phenotype, and this is a transformation of the labium to antennae and a fusion of the first thoracic segment to the head. Interestingly, the labium to antennae transformation is observed in other insects only when both *pb* and *Scr* are removed. The second phenotypic class of *Cx* is more complicated, causing the labium to acquire a maxillary identity, and a duplication of the first thoracic segment. The reason for this transformation is unclear.

1.8.2.2.5. *Antennapedia* (*Antp*) The namesake of the *Drosophila ANT-C* (Kaufman *et al*., 1980), *Antp*, is required for second thoracic identity and leg development. The *Antp* gene includes a total of eight exons, with two promoters (P1 and P2) producing four different sized transcripts (Bermingham and Scott, 1988). The genomic region controlled by P1 is 103 kb while that of P2 is 36 kb. The *Antp* open reading frame, approximately 1.1 kb in length, is found within the last four exons, which encode a protein of about 43 kDa (Schneuwly *et al*., 1986). The homeodomain is encoded within the last exon. Multiple translation start sites and alternative splicing lead to at least four protein isoforms, but these vary only slightly, by up to 17 codons (Carroll *et al*., 1986; Bermingham and Scott, 1988).

In the embryo, *Antp* expression overlaps with *Scr* in the first thoracic epidermis. Though transcripts are detected earlier (Levine *et al*., 1983), the Antp protein is not detectable until germ band extension (Carroll *et al*., 1986). At this time, the protein is weakly detected in the in the anterior ventrolateral portion of the presumptive thoracic region. Initial expression is parasegmental, extending from parasegment 3 to parasegment 6. Expression is dynamic and quickly resolves to include the posterior first thoracic segment and all of the second and third thoracic ectoderm. Expression in the visceral mesoderm begins during late germ band contraction, accumulating posterior to Scr, although not directly abutting it, and coinciding with parasegments 5 and 6. CNS expression initiates during early neurogenesis, with protein accumulating in the VNC from parasegments 4 through 12 (Carroll *et al*., 1986; Wirz *et al*., 1986). As the VNC contracts, Antp expression intensifies in the thoracic region, while the abdominal segments maintain only weak expression (Carroll *et al*., 1986). Bermingham *et al*. (1990) constructed transcript-specific probes and demonstrated that the two promoters are differentially expressed during embryogenesis and have complex (both spatial and temporal) and differing expression patterns.

Transcript and protein accumulation have also been examined at the larval stages, and *Antp* transcripts persist in the ventral neuromere of the second thoracic segment and in the anterior spiracle (Levine *et al*., 1983; Wirz *et al*., 1986). Later, in third instar larvae, Antp accumulates in the humeral imaginal discs, in the wing blade portion of the wing imaginal discs, in portions of the haltere discs and, to some extent, in all of the leg discs (posterior compartment of the first thoracic leg discs and anterior compartment of the second and third thoracic leg discs).

Interestingly, there is differential expression of the P1 and P2 transcripts in the imaginal discs. The P1 transcripts localize to the anterior margins of the second thoracic wing and leg discs, while the P2 transcripts are evenly distributed in these tissues. Both transcripts are detected in the first and third thoracic leg discs (Jorgenson and Garber, 1987). Somatic clonal analysis reveals different developmental requirements for each *Antp* transcript (Abbott and Kaufman, 1986). Proper development of the adult dorsal thorax requires P1 promoter function, while the P2 transcript is required for appropriate leg and embryonic patterning.

There are three classes of dominant gain-of-function mutations within *Antp*, which often result from chromosomal rearrangements causing *Antp* expression outside its normal expression domain. Best known is a mutation responsible for the transformation of the adult antennae toward a second thoracic leg (**Figure 6d**). However, other mutations also transform dorsal head structures toward dorsal thoracic structures (Scott *et al*., 1983), and the *Scr* class transforms the second and third thoracic legs toward a first thoracic identity.

Most dominant *Antp* alleles are also recessive embryonic lethals when hemizygous or heterozygous with an *Antp* null allele. The thoracic cuticle of embryos lacking all *Antp* function is transformed to a more anterior identity (Wakimoto *et al*., 1984). Sclerotic plates resembling mouthpart material are occasionally present in the posterior of the

first thoracic segment, and the denticle belts of the second and third thoracic segments are transformed to resemble those of the first thoracic segment (**Figure 6f**). The fact that sclerotized structures form in the posterior of the first thoracic segment indicates a transformation towards a gnathal identity, while the more posterior thoracic segments adopt a first thoracic identity.

Clonal analysis was used to assess the adult requirement of *Antp* (Struhl, 1981). When clones are induced in the second thoracic leg discs, proximal and medial portions of the second thoracic legs are transformed into the corresponding portions of the antenna. The distal tarsus develops normally, however.

Hayward *et al.* (1995) compared the expression of *Drosophila Antp* to that of the grasshopper and found that, while the pattern of expression is conserved, the initial accumulation is quite different. The anterior limit in the grasshopper is segmental, corresponding to the labial/first thoracic border and, therefore, potentially would be overlapping with Scr, if Scr expression in the grasshopper occurs as in *Drosophila*. Additionally, in the grasshopper, early epithelial thoracic and CNS expression is not as widely modulated as in *Drosophila*, although the expression patterns become more similar later in development with the exception of the modulation that is observed in *Drosophila*.

Expression at the germ band stage is quite similar in all insects examined. The *Tribolium* homolog of *Antp* is called *prothoraxless* (*ptl*); Beeman *et al.*, 1989, 1993), and larvae homozygous for this null mutation bear legs that are transformed to antennae. The dorsal thorax is also significantly reduced. This differs from the effects observed in *Antp* mutants in *Drosophila*, which have a more limited leg transformation. An *Antp* mutant (*Nc*) has been also recovered in *Bombyx*, which results in the transformation of the first thoracic legs to antennae (Nagata *et al.*, 1996). Less extensive changes are also observed in the second thoracic legs, and the silk glands fail to develop properly.

1.8.2.3. The *HOM-C* Genes of the *BX-C*

The genes of the *Drosophila BX-C* govern pattern formation in the posterior thoracic and abdominal regions (**Figure 2**). The *BX-C* spans approximately 350 kb (Martin *et al.*, 1995) and is separated from the *ANT-C* by approximately 7.5 Mb (Martinez and Amemiya, 2002) (**Figure 7**).

1.8.2.3.1. *Ultrabithorax* (*Ubx*) The most proximal gene of the *Drosophila BX-C* is *Ultrabithorax* (*Ubx*), which functions as a major determinant of segment identity in the thoracic and abdominal region by initiating abdominal development and repressing appendage development (Castelli-Gair and Akam, 1995). The *Ubx* gene spans a genomic region of approximately 76 kb (O'Conner *et al.*, 1988) and produces two transcripts, 3.2 and 4.6 kb in size, which vary at the 3′ end due to alternate transcription termination signals. There are four exons including two microexons. The *Ubx* gene encodes at least five different protein variants, but the largest and smallest differ by only 43 amino acids.

Ultrabithorax transcripts are first detected in the syncytial blastoderm (Akam and Marinez-Arias, 1985) and their abundance increases as cellularization proceeds. By gastrulation, a region of strong accumulation includes the primordia of the third thoracic and first abdominal segments, or parasegment 6, with weaker pair-rule-like expression in parasegments 8, 10, and 12. After germ band extension, *Ubx*

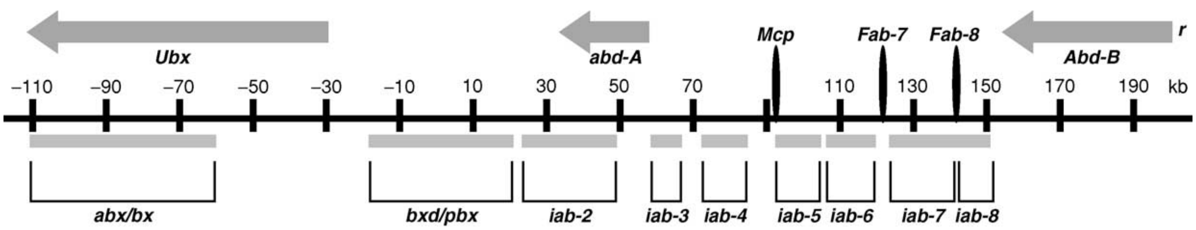

Figure 7 The organization and *cis*-regulatory control regions of the *Bithorax Complex*. The horizontal line, represents approximately 320 kb of the *BX-C* region. The transcription units are marked above the horizontal line for each *BX-C* gene product: *Ultrabithorax* (*Ubx*), *abdominal-A* (*abd-A*), and *Abdominal-B* (*Abd-B*). The *BX-C cis*-regulatory regions are indicated below the horizontal line. The *abx/bx* (*anterobithorax/bithorax*) and *bxd/px* (*bithoraxoid/postbithorax*) regions are involved in *Ubx* regulation. The *infra abdominal control* (*iab*) regions regulate the expression of *abd-A* and *Abd-B*. Three chromatin insulator regions are also shown – *Mcp* (*Miscadastral pigmentation*), *Fab-7* (*Frontoabdominal*), and *Fab-8* – which prevent interactions between neighboring *cis*-regulatory regions. The zero point represents the point of initiation of a chromosome walk by Bender *et al.* (1983). The genomic regions Contributing to the *m* and *r* transcripts of *Abd-B* are also shown.

transcripts are present in parasegments 6 through 12; however, there is greater accumulation in the posterior portion of each parasegment. This is complementary to the expression of *abd-A* in these parasegments (see Section 1.8.2.3.2). Expression in the somatic and visceral mesoderm (parasegment 7, immediately adjacent to *Antp*) (Tremml and Bienz, 1989) begins as the germ band contracts. In the CNS, *Ubx* transcripts are present in the neuromeres, from parasegments 5 through 12 (Akam and Marinez-Arias, 1985). Although lagging transcription by 1–2 h, protein distribution generally follows the patterns of transcript accumulation (White and Wilcox, 1984; Beachy *et al*., 1985).

In larvae, Ubx protein accumulates weakly in the wing and second leg discs, but more strongly in the haltere and third leg imaginal discs (Beachy *et al*., 1985). Pupal expression is limited to the anterior compartment of the first abdominal segment and does not overlap with expression of other *BX-C* genes (Kopp and Duncan, 2002).

Homozygous null *Ubx* individuals die as larvae, with transformation of the third thoracic and first abdominal segments to a second thoracic identity (Lewis, 1978). Individuals hemizygous for viable combinations of *Ubx* alleles give rise to the famous "four-winged fly," as the haltere is transformed to wing (**Figure 1**). In addition to ectopic wings, a wide band of notal tissue forms in the third thoracic segment, and third thoracic legs and thoracic pits can appear on the first abdominal segment. Gain-of-function alleles ectopically expressing *Ubx* exhibit a transformation of the adult second thoracic segment toward a third thoracic identity, causing a partial wing to haltere transformation (Bender *et al*., 1983). Interestingly, there appears to be a temporal component to Ubx function, as null clones induced at different times in development have different effects. Clones induced earlier than 8 h AEL transform the posterior compartments of the second and third legs towards a first thoracic leg identity, while clones induced later than 8 h AEL have normal second legs, but transform dorsal and ventral appendages of the third thoracic segment (haltere and third leg) towards the corresponding appendage of the second thoracic segment (wing and second leg) (Morata and Kerridge, 1981; Struhl, 1982).

Ubx expression and function have been examined in other insects, and there are some differences when compared with *Drosophila*. In the lepidopterans *P. coenia* and *Manduca sexta*, there are circular clearings within the Ubx and Abd-A domains, where the larval prolegs will form (Suzuki and Palopoli, 2001), supporting a role for Ubx in limb suppression. Interestingly, even though sawfly (*Neodiprion*) larvae also develop prolegs, Ubx and Abd-A proteins are detected throughout the developing prolegs, perhaps implying a convergent mechanism for proleg development. This is discussed further, when we consider *HOM-C* target genes. In *Tribolium*, *Ultrathorax* (*Utx*; the *Tribolium* homolog of *Ubx*) expression is initially detected in parasegments 4 and 5, but this expression later resolves to parasegment 5, more similar to the fly (Bennett *et al*., 1999). Genetic analysis uncovered a haploinsufficient *Utx* phenotype, demonstrating that the gene is required for proper development of the adult elytra. Heterozygous adults have warped, blistered elytra that fail to meet at the dorsal midline. Homozygosity is lethal and, similar to flies, the first abdominal and third thoracic segments are transformed to a second thoracic identity.

1.8.2.3.2. *abdominal-A* (*abd-A*) The *abd-A* gene spans a genomic region of approximately 60 kb, with the transcribed region consisting of at least eight exons (Karch *et al*., 1990). This gene is required for the promotion of abdominal development and the suppression of thoracic development in parasegments 7 through 9, for the patterning of parasegments 10 through 13, and the specification of the heart cell fate (Busturia *et al*., 1989; Lovato *et al*., 2002) (see **Chapter 2.6**). The gene encodes a single protein, which is 330 amino acids in length (Cumberledge *et al*., 1990).

Abd-A protein accumulates simultaneously in the first through eighth abdominal segments and in the amnioserosa at about 4 h AEL, during germ band extension, although the mRNA can be detected earlier (Macías *et al*., 1990). The anterior expression border coincides with parasegment 7, but the posterior border of expression appears to be segmental, laterally, extending through the seventh abdominal segment. Ventrally, the posterior expression boundary does not coincide with a compartment border but ends within the posterior region of parasegment 13. There is a gradient of Abd-A accumulation within each parasegment, such that the highest amount of protein occurs at the anterior border of each parasegment fading to nearly complete absence at the posterior border. This pattern is complementary to Ubx in parasegments 7–12, with Ubx being strongest where Abd-A is absent. Maximum Abd-A accumulation occurs in the segmental grooves, but is restricted to only the anterior side of the seventh and eighth segmental grooves. Accumulation of Abd-A is also strong around the tracheal pits.

In the visceral mesoderm, Abd-A is evident in cells abutting those cells expressing Ubx, and extends posteriorly to the end of the visceral midgut mesoderm (Tremml and Bienz, 1989; Karch *et al.*, 1990). In the CNS, Abd-A accumulation reflects the pattern in the epidermis (Karch *et al.*, 1990; Macías *et al.*, 1990). Strong expression is evident in the dorsal vessel, in the cells that will form the posterior portion of the heart (Lovato *et al.*, 2002). Somatic cells of the developing gonad also stain weakly in late embryos (Karch *et al.*, 1990). In pupae, Abd-A accumulates in parasegments 7–12, gradually increasing in amount from anterior to posterior. Its domain is adjacent and nonoverlapping to that of Ubx, in contrast to the overlapping domains observed during embryonic development (Kopp and Duncan, 2002).

Defining homeosis within the abdominal segments is difficult, due to the morphological similarities between these segments, in both the larva and the adult (Mathog, 1991). Null alleles of *adb-A* are embryonic lethals, with abdominal parasegments 7 through 9 completely transformed and parasegments 10 through 13 weakly transformed to a parasegment 6 identity. Hemizygous viable alleles allow the characterization of *abd-A* reduction in adult flies, where the second, third, and fourth abdominal segments are weakly transformed toward the first abdominal segment, with the second abdominal segment being most affected. In addition to mutations disrupting the coding region of the gene or affecting the entire *abd-A* locus, some mutations disrupt *cis*-regulatory elements and affect expression of *abd-A* in specific parasegments (Busturia *et al.*, 1989; Karch *et al.*, 1990). Dominant gain-of-function mutations often result from changes in the *infra abdominal control* (*iab*) regulatory regions, leading to ectopic expression of *abd-A* (Busturia *et al.*, 1989) and affecting adult development (**Figure 7**). For example, one allele, *abd-A*$^{iab2\text{-}S3}$, causes a partial transformation of the first abdominal segment towards a more posterior, second abdominal identity. Other regulatory mutations cause reciprocal transformations of the first abdominal segment towards the second, and the second abdominal segment towards the first (e.g., *abd-A*$^{iab2\text{-}uab1}$). These mutations allow ectopic expression of Abd-A in the developing first abdominal segment, while at the same time reducing Abd-A expression in the developing second abdominal segment. Both of these later mutations only affect imaginally derived tissues. A third gain-of-function allele, *abd-A*$^{iab3\text{-}277}$, causes a divergent transformation, with the first abdominal and third through fifth abdominal segments being all transformed to a second abdominal identity.

While the ninth and tenth abdominal segments in *Drosophila* are quite reduced, many lower insects have ten full abdominal segments. Expression of *abd-A* homologs reflects this anatomical difference. In *Tribolium*, *Abdominal* (*A*) (the homolog of *abd-A*) has a broader pattern of posterior abdominal expression, reflecting the increased number of abdominal segments (Stuart *et al.*, 1993; Shippy *et al.*, 1998). In *A* mutants, all abdominal segments develop pleuropodia in their anterior compartment (normally only found in the first abdominal segment) and protrusions with a posterior third thoracic leg identity in their posterior compartment. In *Bombyx*, loss of the *abd-A* homologue (E^{Ca}) is thought to cause a transformation of the second through seventh abdominal segments to a more anterior abdominal identity (Ueno *et al.*, 1992). Larval prolegs are normally present on the third through sixth abdominal segments, but not on the first, second, and seventh segments. In E^{Ca} mutants, the prolegs are lost from the third through the sixth abdominal segments. Although the exact identity of the transformed segments is not clear, one expects an anterior transformation to a first abdominal identity, by analogy to the role of *adb-A* in *Drosophila*. Another mutation in *Bombyx*, E^N, removes both the *Ubx* and *abd-A* homologs. Larvae homozygous for this allele develop thoracic-type legs in the first through the seventh abdominal segments with a mixed leg/proleg identity in the eighth abdominal segment. This transformation to a more anterior identity supports the proposed anterior transformation in the E^{Ca} mutants.

1.8.2.3.3. *Abdominal* B (*Abd-B*) *Abd-B* governs the development of the most posterior abdominal segments of *Drosophila*, and limits the size of the *Drosophila* abdomen by repressing *abd-A* function. The *Abd-B* gene spans approximately 100 kb, containing at least eight exons with multiple promoters. The homeobox is encoded by exons seven and eight, and the position of the intronic interruption is the same as in *lab* and *pb*. Five transcripts are produced, ranging in length from 3.3 to 7.8 kb, with each transcript sharing four common exons (Kuziora and McGinnis, 1988a). These transcripts are expressed in specific spatial and temporal patterns.

The *Abd-B* gene encodes two distinct homeoproteins of 54 and 36 kDa (Celniker *et al.*, 1989), referred to as the “m” and “r” forms, respectively (**Figure 7**). The m form has a morphogenetic role in parasegments 10–13, specifying identity in the posterior abdominal segments. The r form has a regulatory function. It suppresses the m protein’s morphogenic role in parasegment 14 and possibly

limits abdominal segmentation (Casanova *et al.*, 1986; Boulet *et al.*, 1991; Kuhn *et al.*, 1995). The r protein form lacks a glutamine-rich M- or opa-repeat (Wharton *et al.*, 1985), which is a transcription activation domain that is found in the m form. The 7.8, 3.7, and 3.3 kb transcripts encode the r protein and accumulate in parasegments 14 and 15, while the 4.3 and 4.7 kb transcripts encode the m protein and accumulate in parasegments 10 through 15 (Celniker *et al.*, 1989; Zavortink and Sakonju, 1989).

The Abd-B proteins are first detectable in the posterior ectoderm of parasegments 13 through 15 of early germ band extended embryos. Relative to the detection of the transcripts, the protein is delayed by approximately 1.5–2 h (Celniker *et al.*, 1989; Delorenzi and Bienz, 1990). As embryogenesis continues, Abd-B expression spreads anteriorly into portions of parasegments 11 and 12. There is a stepwise increase in protein concentration towards the posterior region of the embryo. During early germ band retraction, visceral mesodermal expression is first detected laterally in parasegments 12 through 14 of the mesoderm (Tremml and Bienz, 1989). Expression in the VNC is also evident during this period, and follows the pattern of the epidermis (Celniker *et al.*, 1989; Delorenzi and Bienz, 1990). Following head involution, protein accumulation fades and is not detectable again until the third instar larval stage (in the genital discs). Expression returns to the abdominal segments in pupae, and is found at progressively higher levels in the fifth through seventh abdominal segments (Kopp and Duncan, 2002).

Although the antibody used to detect Abd-B protein recognizes both the m and r forms, *iab-8* mutants are m^-, so protein accumulation in these embryos allows inference of the r form's expression pattern in parasegments 14 and 15 and in the mesoderm of parasegment 14. The anterior margin of the r protein is unchanging during development, always coinciding with the border of parasegments 13 and 14. This differs from the shifting anterior margin observed with this antibody in wild-type embryos, when both forms of the protein are present and detected. It is likely that all of the Abd-B protein detected anteriorly to parasegment 14 corresponds to the m protein. Embryos lacking the r form have a wild-type protein accumulation pattern, reflecting normal m protein in parasegments 10 through 13, and ectopic m protein in parasegment 14 that is due to its derepression by the lack of the r function (Delorenzi and Bienz, 1990).

Loss of *Abd-B* function is lethal and causes the transformation of all abdominal segments posterior to the fifth abdominal segment to a fourth or fifth abdominal cuticle pattern (Sánchez-Herrero *et al.*, 1985). Exact identification is difficult, again, due to similarity between these segments. Also, the larval posterior spiracles are reduced or eliminated. Some homozygous lethal alleles produce a few escapers, allowing the adult effects of *Abd-B* loss to be directly assessed. In adults, the fifth through eighth abdominal segments are transformed to a fourth abdominal identity. The dominant haploinsufficient effects of *Abd-B* are weak transformations of the sixth and seventh abdominal tergites which resemble the fourth or fifth abdominal type, and adult infertility.

Absence of Abd-B in the genital disc results in a transformation of the male and female genitalia to leg, with claws, tarsi, and/or tibia (Estrada and Sánchez-Herrero, 2001). Less frequently, there was a transformation towards antennae, producing second and/or third antennal segments and arista.

In *Drosophila Abd-B* mutants, a full ninth abdominal segment develops concomitant with posterior expansion of *abd-A* expression (Casanova *et al.*, 1986; Karch *et al.*, 1990). This, and comparisons with other insects, has led to the proposal that *Abd-B* sets the limit on the number of abdominal segments to be formed by repressing *abd-A* activity (Hughes and Kaufman, 2002). The *Tribolium Abd-B* homolog, *extra urogomphi* (*eu*), has a more limited expression than *Abd-B*, corresponding only to the posteriormost segments (the tenth and eleventh abdominal segments), whereas *Drosophila Abd-B* is found in approximately five abdominal segments. However, the results from *Thermobia* and *Schistocerca* may contradict this model. *Schistocerca* has a limited *Abd-B* expression domain initially (only the eleventh abdominal segment), but later expression expands anteriorly through the posterior eighth abdominal segment (Kelsh *et al.*, 1993). In *Thermobia*, the *Abd-B* homolog (*TdAbd-B*) is initially expressed posterior to the growth zone, behind the forming posterior abdominal segments (Peterson *et al.*, 1999), but extends anteriorly into the eighth abdominal segment after germ band extension.

The anterior expression in *Thermobia* and *Schistocerca* is perhaps contrary to the model predicting that extended *Abd-B* expression limits the number of abdominal segments, except that this expansion occurs after *abd-A* has been expressed in these segments. Interestingly, the domains of *Abd-B* homolog expression in other insects is similar to the expression pattern of the r-type *Drosophila* protein, while the expression domains coinciding with the *Drosophila* m-type protein appear to be absent.

Also of interest is the difference between *TdAbd-B* expression from that of other *Thermobia HOX* genes, in the limbs that develop in each gene's expression domain. The *Thermobia* homologs of *pb, Dfd, Scr, Antp*, and *Ubx* are expressed throughout the limbs developing in their segments, while *TdAbd-B* is only expressed in the cercal appendage primordia, and not in the appendages themselves as they develop (Peterson *et al*., 1999). A similar lack of expression is noted in the cercal appendages of *Schistocerca* (Kelsh *et al*., 1993). Peterson *et al.* (1999) propose that this may indicate a fundamental difference in the nature of terminal appendages versus anterior appendages.

A final interesting note is the association of *Abd-B* with genital development, a role conserved in other insects, spiders (Damen and Tautz, 1999), and even vertebrates, suggesting a general role in establishing the genitalia (Akam *et al*., 1988).

1.8.2.4. *HOX* Expression in Related Arthropods

HOM-C/HOX genes expression has been examined in several noninsect arthropods. Expression has been examined in crustaceans, chelicerates (spiders and mites), and myriapods (centipedes) and significant variations were found from the expression patterns observed in insects. These have been reviewed by Hughes and Kaufman (2002), who also discuss the evolutionary implications of the variability of these genes in arthropod body patterning.

1.8.3. Regulation of *HOM-C* Gene Function

1.8.3.1. Introduction

The *HOM-C* genes' clustered genomic structure and collinear expression are rather uniquely conserved across phyla. This raises the question: why are the *HOM-C/HOX* genes found in such highly conserved arrangements, and is this a requirement for their expression and function? Studies in vertebrates reveal shared *HOX* regulatory regions and indicate that changes in the arrangement of the complex can impact the expression of multiple *HOX* genes (Gould *et al*., 1997; Sharpe *et al*., 1998). The fact that splits in the *HOM-C/HOX* cluster have only been observed (thus far) in *Drosophila* and in the nematode *Caenorhabditis elegans* (Ruvkun and Hobert, 1998), suggests a strong evolutionary constraint for the ordered *HOM-C/HOX* cluster, and perhaps a loosening of this constraint in these two organisms, in which shared *HOM-C* gene regulatory regions have not been identified. The conservation of ordered, clustered genomic organization may be required for the temporal and spatial collinearity observed in *HOM-C* expression (van der Hoeven *et al*., 1996; Kondo and Duboule, 1999), but the mechanism underlying this requirement has yet to be determined (review: Kmita and Duboule, 2003). In spite of the existing uncertainties, however, some of the mechanisms of *HOM-C* gene regulation in *Drosophila* are understood.

As seen by their mutant phenotypes, the HOM-C proteins are powerful transcription factors, directing the downstream expression of other genes in specifying developmental pathways. Loss or misexpression of a *HOM-C* gene is sufficient to direct cells, and even whole body regions, towards dramatically different developmental fates. Frequently, these changes in expression are lethal and accompanied by gross morphological defects, and even when viable adults are produced, fitness may be greatly effected. Therefore, strict spatial and temporal control of the *HOM-C* selector genes is critical to normal body patterning. Interestingly, and perhaps predictably, alterations in *HOM-C* gene expression appear to play a role in the differential body patterning between some insect species.

The transcriptional control of the *Drosophila HOM-C* genes can be exercised at two levels, related to (1) the initiation or establishment of the active state, and (2) the maintenance of this state. This is true whether we are discussing activation or repression. Initiation or establishment of *HOM-C* gene activity is generally a short term phenomenon and, where mapped, involves local regulatory elements within close proximity to the promoters (Bienz and Müller, 1995). *Trans*-acting factors that initiate *HOM-C* expression include gap and pair rule segmentation gene products. The maintenance phase is long term and may involve DNA elements that are a large distance away from the promoter. Two protein groups, the Polycomb and the Trithorax groups, have opposing effects on the long-term regulation of *HOM-C* transcription. Self-regulation by the *HOM-C* genes and cross-regulation between *HOM-C* genes are also important to the regulation of *HOM-C* gene activity.

A summary of the regulatory factors discussed in this chapter is shown in **Table 1**.

1.8.3.2. Initiation and Establishment of *HOM-C* Gene Expression

In the *Drosophila* embryo, the establishment of early *HOM-C* expression occurs during the syncytial or early cellular blastoderm stage and is controlled by the early upstream gap and segmentation gene products. Several studies have demonstrated regulation of *HOM-C* gene expression by the gap

brahma (brm)		
moria (mor)		
Snf5-related 1 (Snr1)		
eyelid/osa (*osa*)		

[a]Note that *Drosophila* gene names follow a standard nomenclature: genes are generally named for the mutant phenotype, and dominant mutations are capitalized whereas recessive mutations are lowercase and are shown in italics. Protein names are generally capitalized and not italicized.

gene products. For example, Gap proteins regulate the expression of the *abd-A* and *Abd-B* genes through the *infra-abdominal* (*iab*) regions (**Figure 7**), which represent *cis*-regulatory regions of the *abd-A* and *Abd-B* genes (Casares and Sánchez-Herrero, 1995). The number following the *iab* abbreviation reflects the abdominal segment in which each region has its most prominent regulatory effect. For example, the *iab-5*, *iab-6*, *iab-7*, and *iab-8* *cis*-regulatory regions control *Abd-B* expression in segments 5, 6, 7, and 8, respectively. The *iab* regions, which do not produce protein-coding mRNAs, are transcribed initially at the blastoderm stage, and the anterior limits of their expression are collinear with the chromosomal location of each region (Sánchez-Herrero and Akam, 1989; Cumberledge *et al*., 1990). When fused to *lac-Z* reporter genes, the *iab* regions direct expression in precise and distinct domains (Simon *et al*., 1990; Galloni *et al*., 1993; McCall *et al*., 1994; Zhou and Levine, 1999; Barges *et al*., 2000). Their function appears to be the integration of positional information from the Gap proteins and the transmission of this information into specific regional *abd-A* and *Abd-B* activation domains. It has been proposed that the transcription of these regions "opens" the *abd-A* and *Abd-B* regions to allow activation (Gyurkovics *et al*., 1990).

The protein products of the gap genes *hunchback* (*hb*), *Krüppel* (*Kr*), *tailless* (*tll*), and *knirps* (*kni*) control early *abd-A* and *Abd-B* expression through the selective regulation of the *iab* regions (Casares and Sánchez-Herrero, 1995; Shimell *et al*., 2000). Loss of either Hb or Kr allows anterior expansion of *iab-2* (via Kr), *iab 3–4* (via Kr and Hb) and *iab 5–6* (via Kr) transcription, and causes a concomitant anterior expansion of *abd-A* and *Abd-B* expression domains (Shimell *et al*., 1994). In this manner, Kr and Hb define the anterior limits of initial *abd-A* and *Abd-B* expression. The Tll protein similarly limits the posterior expression of *abd-A*; loss of Tll allows *abd-A* expression to occur almost to the end of the germ band (Casares and Sánchez-Herrero, 1995). Further, Tll and Kni regulate transcription in the *iab-8* domain and have opposing effects upon *Abd-B* activity. The loss of Kni causes anterior expansion of *Abd-B* expression through an expansion of *iab-8* transcription, while the loss of Tll eliminates *Abd-B* expression. Differing gradients of gap gene products along the anterior–posterior axis may drive the differing spatial regulation of the *iab* regions. The transcription of the *iab* regions is further regulated by chromatin insulator regions (review: Müller, 2000), which intervene between the *iab* elements (**Figure 7**). The loss of a chromatin insulator region allows transcription to occur across *iab* regions, and can result in homeotic transformation of one abdominal segment to another (Mihaly *et al*., 1997, 1998; Drewell *et al*., 2002).

Gap gene products also affect the expression of other *HOM-C* genes. The *cis*-regulatory regions of *Ubx* – *abx/bx* (*anterobithorax/bithorax*) and *bxd/pbx* (*bithoraxoid/postbithorax*) (**Figure 7**) – also require gap gene products for early regulation, although it does not appear that this involves the

transcription of noncoding RNAs (Qian *et al.*, 1993). Additionally, the loss of Hb affects the expression of other *HOM-C* genes functioning within its domain (*Scr*, *Antp*, and *Ubx*) (White and Lehmann, 1986; Riley *et al.*, 1987; Harding and Levine, 1988).

The control of the *ANT-C* gene *Dfd* by early patterning genes has also been investigated (Jack *et al.*, 1988). Early *Dfd* activity is not significantly affected by changes in the zygotic gap genes, but mutations in the pair-rule genes do affect *Dfd* expression. Mutations in *hairy* (*h*), *runt* (*run*), *even-skipped* (*eve*), *fushi tarazu* (*ftz*), *paired* (*prd*), *odd-paired* (*opa*), *odd-skipped* (*odd*), and *engrailed* (*en*), all affect *Dfd* expression. Mutations in *odd* and *ftz* cause a spatial expansion of *Dfd* expression, indicating a negative regulation of *Dfd* by the respective gene products. The remaining mutants result in contracted *Dfd* expression by varying degrees, indicating a role in the early activation of *Dfd*.

These results support a hierarchical mode of regulation, where Gap proteins regulate pair-rule genes, and pair-rule products regulate *HOM-C* genes. Other work, however, suggests a combinatorial role for early patterning genes in *HOM-C* gene regulation. In separate studies investigating the expression patterns of *Scr, Antp* P2, and *Ubx*, Ftz was shown to be required for the initial activation of these *HOM-C* genes (temporal control), while the gap gene products control their spatial domains of expression (Ingham and Martinez-Arías, 1986; Riley *et al.*, 1987; Martinez-Arías and White, 1988). More recent work demonstrates a more direct role for the gap protein Hb in the activation of *Antp*. The authors proposed that this may also be true for the Gap proteins Giant (Gt) and Kr, in terms of the activation of *Scr* and *Ubx*, respectively (Wu *et al.*, 2001). It must be noted, however, that the large-scale morphological defects in Gap gene mutants can confound the assessment of their effects on *HOM-C* expression.

1.8.3.3. Maintenance of *HOM-C* Gene Regulation

The maintenance of *Drosophila HOM-C* gene expression or repression is required beyond the early stages of embryogenesis, after the early patterning gene products are no longer available. Because cells continue to express the *HOM-C* genes in spatially restricted patterns throughout development, the cells must "remember" their *HOM-C* transcription state to avoid inappropriate activation or loss of selector gene function. This long-term retention of *HOM-C* transcription state is controlled by two large groups of *trans*-acting proteins, the Polycomb Group (PcG) (review: Simon, 1995) which maintains the *HOM-C* genes in the repressed state, and the Trithorax (Trx) Group (review: Ingham, 1998) which maintains the genes in the active state. Both the Trx group and PcG group proteins are widely conserved between *Drosophila* and mammals (Müller *et al.*, 1995; Simon, 1995).

The PcG proteins function as long-term repressors of *HOM-C* function (Bienz and Müller, 1995; Jacobs and van Lohuizen, 1999). These proteins form multimeric complexes, which are vital for the maintainance of the spatial boundaries of *HOM-C* gene expression (Franke *et al.*, 1991; Simon *et al.*, 1992). They are expressed throughout the embryo (e.g., Franke *et al.*, 1991; Paro and Zink, 1992; Lonie *et al.*, 1994; Martin and Adler, 1993) and, therefore, cannot on their own, define spatial expression of the *HOM-C* genes (Simon *et al.*, 1995). Rather, these protein complexes maintain the expression state initiated by the earlier segmentation proteins by binding PcG response elements (PREs) found within the *HOM-C* gene regions (Zink and Paro, 1989; Castelli-Gair and Garcia-Bellido, 1990; Simon *et al.*, 1995; Gindhart and Kaufman, 1995; Simon, 1995). In *PcG* mutants, the initial expression of the *HOM-C* genes is normal; however, as early segmentation gene products begin to decay, ectopic expression of the *HOM-C* genes becomes apparent (Wedeen *et al.*, 1986). This leads to homeotic transformations similar to those observed in *ANT-C* and *BX-C* gain of function mutants (e.g., Lewis, 1978; Duncan, 1982; Dura *et al.*, 1985; Choi *et al.*, 2000).

The PcG proteins are thought to mediate repression through the formation of higher-order chromatin structures associated with histone methylation (Cao *et al.*, 2002). The PREs do not have a specific recognizable consensus DNA sequence (Jacobs and van Lohuizen, 1999), and the PcG proteins are likely to be recruited to the PREs by either the repressive Gap or pair-rule proteins, or another DNA binding intermediary.

The Trithorax (Trx) group proteins serve a reciprocal role to the PcG proteins and maintain the active transcriptional state of the *ANT-C* and the *BX-C* genes (Breen and Harte, 1993; Kennison, 1993; Gindhart and Kaufman, 1995). Trithorax (Trx), the namesake and best-characterized member of the group (Ingham and Whittle, 1980), accumulates in a spatially modulated pattern, beginning with pair-rule-like stripes in the posterior of the embryo. This may regulate early *BX-C* transcription (Sedkov *et al.*, 1994), as *trx* mutants have altered *BX-C* gene expression during germ band extension. However, *ANT-C* gene expression is unaltered until the late stages of development.

There are alleles of *trx* that affect late *ANT-C* gene expression with no effect upon *BX-C* expression,

indicating the generation of multiple products, with multiple roles, from the *trx* locus. Null mutants of *trx* mimic loss-of-function mutations in the *ANT-C* and *BX-C* clusters, sometimes producing flies with six dorsal thoracic appendages of wing-like identity, the phenotype for which the gene and the group are named (Ingham, 1998).

Like the case of the PcG proteins, it is suspected that the Trx group proteins may not bind DNA directly, but act through other proteins with DNA binding activity. Interestingly, analysis of PcG and Trx protein localization on salivary gland polytene chromosomes demonstrates that these proteins bind many of the chromosomal regions that contain *ANT-C* and *BX-C*. Thus, interaction between these opposing regulatory proteins at the same chromosomal sites may be important to their function (Kuzin *et al*., 1994; Chinwalla *et al*., 1995). However, it is also important to note that although these protein complexes function to maintain the initial *HOM-C* gene activity state in a particular region, the *HOM-C* genes are by no means "locked in" to a particular activity state for the duration of development. This is evident by the dynamic patterns of expression observed for individual *HOM-C* genes during development (discussed earlier in this chapter).

1.8.3.4. Regulation between the HOM-C Proteins: Auto- and Cross-Regulation

The earliest recognized *Drosophila HOM-C* gene regulation was from proteins encoded within the complexes themselves. The *HOM-C* genes cross regulate one another's activity, and the expression of several of the *HOM-C* genes is partially directed by autoregulatory loops. Several of the HOM-C proteins function to limit the expression of *HOM-C* genes expressed in adjoining regions. For example, Abd-B represses both *Ubx* and *abd-A* to exclude their expression in the posterior abdomen (Macías *et al*., 1990). Abd-A limits the expression of *Ubx*, giving the two BX-C proteins complementary expression patterns in the trunk (Karch *et al*., 1990). Similarly, a high level of Antp in the second thoracic segment, and BX-C proteins in the remaining trunk segments, are required to limit the posterior boundary of *Scr* expression (Riley *et al*., 1987). In the absence of the *BX-C* genes, *Scr* expands its domain posteriorly to include epidermal expression in the posterior compartments of the thoracic and abdominal segments (Pelaz *et al*., 1993). Interestingly, this expansion is dependent upon moderate levels of ectopic Antp (normally repressed by the BX-C proteins), which, in the absence of the BX-C proteins, activates *Scr* in the context of the posterior trunk segments.

In two recent studies, Miller *et al*. (2001a, 2001b) utilized the UAS-Gal4 system (an inducible expression system which makes use of the yeast Gal4 transcriptional activator and its binding site, the Upstream Activation Sequence; Brand and Perrimon, 1993) to investigate the embryonic cross-regulatory relationships of the *HOM-C* genes. They separately focused on cross-regulation in the epidermis, the CNS, the visceral mesoderm, and the somatic mesoderm. In the epidermis, cross-regulation generally follows a hierarchy, whereby the more posterior proteins can repress the activation of the anterior genes, but not vice versa. For example, ectopic expression of Lab is unable to repress the activity of more posteriorly expressed *HOM-C* genes, while ectopic Abd-A protein results in reduced expression of all *HOM-C* genes expressed more anteriorly.

The *HOM-C* genes demonstrate tissue-specific cross-regulatory activities. For example, ectopic Scr and ectopic Dfd activate *pb* in the ectoderm, which is consistent with the normal role for these proteins in activating *pb* expression in the embryo (Rusch and Kaufman, 2000). In the mesoderm, however, ectopic Scr represses the expression of *pb* (Miller *et al*., 2001a). The hierarchy of cross-regulation in the CNS also differs from that in the epidermis. Ectopic Ubx and Abd-A are only able to repress two HOM-C genes (*Scr*, *lab*) in the CNS, whereas Ubx and Abd-A have greater cross-regulatory effects in the epidermis. Miller *et al*. (2001a) conclude that no simple model can describe comprehensively the regulatory relationships between the *HOM-C* genes. Their interactions in the CNS and mesoderm are more complex, and signaling cascades likely contribute to this complexity. Assessment of the relationship between cell autonomous regulation and signal transduction led these authors to propose a new hierarchical relationship in the mesoderm, called "autonomic dominance," in which the extrinsic determination of cell fate via signaling can be overridden by the expression of HOM-C proteins.

The integration of signaling and *HOM-C* gene regulation is illustrated by the induction of HOM-C signaling in the endoderm via signals from the overlying visceral mesoderm. This pathway links the regulation of two *HOM-C* genes indirectly through signaling and feedback loops (Bienz, 1997) (**Figure 8**). Ultrabithorax and Extradenticle (Exd; expressed in the visceral mesoderm) direct this complex pathway by activating the signaling molecules Decapentaplegic (Dpp) and Wingless (Wg). These molecules signal to cells in the endoderm, eventually resulting in the activation of *lab* expression and specification of endodermal cell fate (Immerglück *et al*., 1990; Reuter *et al*., 1990; Staehling-Hampton *et al*.,

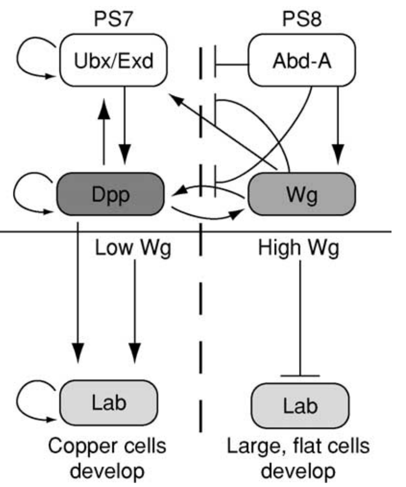

Figure 8 The integration of signaling and *HOM-C* gene regulation in endoderm induction and copper cell specification. Parasegments are approximately six to eight cells wide at the time of endoderm induction. Positive interactions are denoted with arrows, and repressive ones are denoted with bars. In parasegment 7, Ubx/Exd directly induces *dpp* expression in the visceral mesoderm overlying the presumptive endoderm. Dpp signaling results in a band of *Wg* expression in the visceral mesoderm of parasegment 8. The levels of Wg signaling modulate the position of *labial* expression in the endoderm. High levels of Wg in parasegment 8 repress the activation of *labial* and allow the development of large, flat endodermal cells. In parasegment 7, signaling input from Dpp and low levels of Wg activate *labial* and the subsequent specification of crescent-shaped endodermal copper cells. Both Wg and Abd-A repress *Ubx* transcription in parasegment 8, contributing to the spatial limitation of copper cell differentiation to the endoderm of parasegment 7. Numerous autoregulatory and feedback loops act in this pathway: both Dpp and Wg act synergistically to maintain *Ubx* expression; *Ubx*, *dpp* and *lab*, all demonstrate autoactivation; and Ubx feeds back on Dpp to maintain *dpp* expression in the midgut.

1994; Sun *et al*., 1995; Eresh *et al*., 1997; Grieder *et al*., 1997). The concentration of Wg directs the activity state of *lab* in these cells. Low Wg levels promote *lab* activation and endodermal copper cell differentiation. High levels of Wg, on the other hand, repress *lab* activation and, thus, repress the differentiation of copper cells (Hoppler and Bienz, 1995). This regulation may be mediated through the Wg signal transducers, such as *disheveled* (*dsh*), *armadillo* (*arm*), and *shaggy* (*sgg*), and clearly illustrates a link between differential regulation of a *HOM-C* gene and a specific terminal cell fate.

Autoregulation can also direct the activity of the *HOM-C* genes. Some of the earliest characterized HOM-C protein binding sites were autoregulatory elements. Several regionally specific autoregulatory elements have been characterized in *Dfd, Ubx,* and *lab* (Bienz and Tremml, 1988; Kuziora and McGinnis, 1988b; Bergson and McGinnis, 1990; Chouinard and Kaufman, 1991; Regulski *et al*., 1991). These elements may be located upstream of the promoter or within intronic regions. For example, a CNS-specific autoregulatory element of *Dfd* maps within the large *Dfd* intron (Lou *et al*., 1995), while an epidermal enhancer resides upstream of the *Dfd* promoter (Bergson and McGinnis, 1990; Zeng *et al*., 1994).

1.8.3.5. Posterior Prevalence–Functional Hierarchies

Posterior prevalence, also called functional dominance and phenotypic suppression, refers to the phenomenon whereby a posteriorly expressed protein can override the function of a more anteriorly functioning protein, when these are simultaneously expressed in the same cells. For example, the ubiquitous ectopic expression of Scr, under the control of a heat shock promoter, is lethal and results in the transformation of the embryonic maxillary segment towards a labial identity, as evidence by the partial loss of mouthpart structures and the formation of ectopic salivary glands (Zeng *et al*., 1993). The Scr protein overrides the normal patterning directed by Dfd in the mandibular and maxillary lobes. This could be due to a higher level of Scr than Dfd in these regions. However, there is no phenotypic effect in the trunk posterior to the second thoracic segment. Ectopic Scr appears unable to supersede the functions of endogenous Ubx, Abd-A, and Abd-B, even though these proteins are probably less abundant. Similarly, the ubiquitous ectopic expression of Ubx causes the transformation of segments anterior to the first abdominal, including the development of abdominal type denticles in the head and in the thorax (González-Reyes and Morata, 1990). However, segments posterior to the first abdominal are not altered. Therefore, like Scr, Ubx is unable to override Abd-A and Abd-B function in the epidermis.

There are, however, violations to the posterior prevalence model. For example, the ectopic expression of Dfd is able to induce ectopic mouth hooks in the labial segment, alter the denticle patterning of the second thoracic segment to resemble the first thoracic segment, and produce ectopic sensory cirri and sclerotized mouthpart-like material in the trunk segments (Kuziora and McGinnis, 1988a), thus apparently altering the patterns directed by the endogenous HOM-C proteins in these cells.

1.8.3.6. Regulation of HOM-C Protein Function by Phosphorylation

Not all *HOM-C* gene regulation occurs at the level of transcription; HOM-C protein function is also

modulated posttranslationally. The N-terminal portion of the homeodomain is important for the specificity of homeodomain function (see Section 1.8.4), and this region of the Scr protein is a target for a regulatory subunit of the serine–threonine specific protein phosphatase 2A (dPP2A, B′) (Berry and Gehring, 2000). The phosphorylation state of two key residues in the N-terminal portion of the homeodomain (Thr6 and Ser7) is critical to Scr function. These residues can be phosphorylated by cAMP-dependent kinase A (PKA), and dephosphorylated by dPP2A in cultured cells. Ectopic expression of an Scr protein construct mimicking constitutive dephosphorylation (with Thr6 and Ser7 altered to alanine), reproduces the embryonic phenotype induced by ectopic expression of the wild-type protein (loss of some mouthpart structures, ectopic salivary gland formation, and transformation of the second and third thoracic segments towards a first thoracic identity). Conversely, an ectopically expressed Scr protein construct, in which Thr6 and Ser7 are altered to mimic constitutive phosphorylation (by substitution with aspartic acid) is unable to reproduce the embryonic ectopic Scr phenotype and has a reduced ability to bind a target DNA sequence *in vitro*. Further, dPP2A,B′ appears to be required for endogenous Scr function, as embryos lacking dPP2A,B′ fail to form salivary glands.

A second example of HOM-C protein functional regulation by phosphorylation involves Antp. Phosphorylation by the serine–threonine kinase casein kinase II (CKII) is implicated in preventing spatially inappropriate Antp function during *Drosophila* embryogenesis (Jaffe *et al*., 1997). Together, these results suggest that posttranslational modifications may control the functional state of a HOM-C protein.

1.8.3.7. Regulation of *HOM-C* Genes in Other Insects

Because *Drosophila* is a long germ insect, patterning its trunk segments from a continuous existing group of cells, aspects of its *HOM-C* gene regulation might be expected to differ from intermediate or short germ insects, which form their trunk segments sequentially from a continuously dividing growth zone. Homologs to many of the *Drosophila* early segmentation genes have been identified, in other insects, and their expression patterns examined. In *Tribolium*, homologs to each class of the *Drosophila* segmentation genes have been identified, and the expression of most was shown to be similar to that observed in *Drosophila* (Sommer and Tautz, 1993; Brown *et al*., 1994; Nagy and Carroll, 1994; Patel *et al*., 1994; Wolff *et al*., 1995; Brown *et al*., 1997). Yet, their function may not always be the same. For example, in *Tribolium*, deletion of *Tcftz* has no effect on segmentation (Stuart *et al*., 1991). Similarly, the homologs of the pair-rule genes *eve* and *ftz* appear to have no pair-rule function in *Schistocerca* (Akam and Dawes, 1992; Patel *et al*., 1992). Differences in the roles of these genes may also reflect differences in their ability to regulate *HOM-C* gene expression, but this remains to be investigated.

One proposed regulator of *HOM-C* gene activity in other insects is the *Tribolium* gene, *jaws*. Mutants in this gene bear a phenotype similar to one resulting from the overexpression of *mxp*, the *Tribolium* homolog of *pb* (Sulston and Anderson, 1998). Embryos lacking *jaws* have a homeotic transformation of the thoracic and anterior abdominal segments into four alternating maxillary and labial segments, and also fail to form a number of posterior abdominal segments (Sulston and Anderson, 1996). The *mxp* gene is ectopically expressed in each transformed segment, with Ultrathorax (the homolog to Ubx) and Abdominal (the homolog to Abd-A) being virtually absent in the few remaining trunk segments. The *jaws* gene is not located within the *Tribolium HOM-C*, and thus is a candidate negative regulator of *HOM-C* gene activity. Sulston and Anderson postulate that *jaws* may represent a member of the *Tribolium Polycomb* group.

Cross-regulation of *HOM-C* genes also is observed in other insects. *Tribolium* shares regulatory relationships between *pb* and *Scr* similar to those present in *Drosophila*. In the *Drosophila* embryo, *Scr* and *Dfd* positively regulate *pb* expression in the gnathal segments (Rusch and Kaufman, 2000), while in the distal region of the larval labial disc, *pb* positively regulates the activity of *Scr* (Abzhanov *et al*., 2001). In *Tribolium*, development of the larval labial appendage requires *Cx* (the *Scr* homolog) to properly activate early and midstage embryonic expression of *mxp* (the *pb* homolog) (DeCamillis *et al*., 2001), and MXP positively regulates *Cx* expression in the distal gnathal appendage fields in later embryonic development (DeCamillis and ffrench-Constant, 2003). However, this does not hold true in all insects. Similar patters of *Scr* and *pb* expression are observed in the milkweed bug, but RNAi experimentation indicates no apparent regulation of *Scr* by *pb* in gnathal appendage buds, or cross-regulation of *pb* by *Scr* (Hughes and Kaufman, 2000). It is clear therefore, that there may be differences in *HOM-C* regulation, and this is an area where additional information from other insects is needed.

1.8.4. The Homeobox and the Homeodomain: Identification, Structure, and Function

1.8.4.1. Identification and Characterization of the Homeobox and Homeodomain

Following the cloning of the *ANT-C* and *BX-C*, two groups identified a strongly conserved DNA sequence in several genes within the two complexes, which was called the H-repeat (McGinnis *et al.* 1984b; Scott and Weiner, 1985). Further testing pinpointed their genomic locations to regions within the *BX-C* (between the *bxd/pxd* and *iab-2* mutations) and the *ANT-C* (in the region of *pb*, *Dfd*, and *zen*). The H-repeat was named the "homeobox," and a second conserved repeated sequence, the M-repeat, was also identified. The M-repeat encodes a poly-glutamine repeat that had been previously identified in genes outside of the *HOM-C*, and is alternatively called the opa-repeat (Wharton *et al.*, 1985). Sequence analysis revealed strong conservation of predicted amino acid sequence between the gene regions. Using the homeobox sequences from *Antp* and *Ubx*, Regulski and collaborators mapped homeobox sequences to each *ANT-C* gene cloned at the time (*ftz, Antp, Dfd*, and *Scr*) and to three regions within the *BX-C* (*Ubx, abd-A*, and *Abd-B*) (Regulski *et al.*, 1985). They concluded, "all of the copies of homeobox homology that are well conserved with respect to both *Antp* and *Ubx* copies, map within genes of the *ANT-C* or *BX-C*." Later work showed that both *pb* and *lab* are also homeobox and M-repeat containing genes (Mlodzik *et al.*, 1988).

The homeobox is a nucleotide sequence of 180 well-conserved base pairs, encoding a 60 amino acid motif called the homeodomain (Figure 9) (McGinnis *et al.*, 1984c). Within the homeobox, nucleotide sequence similarities among the *HOM-C* genes are as high as 75–80%, and many of the nucleotide differences are silent. For example, *Antp* and *Ubx* share 79% nucleotide identity within the homeobox, but share 89% amino acid identity in the homeodomain. Outside of the 180 bp region, the sequence similarity among the *HOM-C* genes is limited to small regions, or is nonexistent.

Evolutionary conservation of the homeobox was initially reported in the genomes of three other segmented invertebrates (*D. hydei*, the beetle *Tenebrio molitor*, and the earthworm *Lumbricus* sp.) and three vertebrates (chicken, frog *Xenopus laevis*, and mouse) (Carrasco *et al.*, 1984; McGinnis *et al.*, 1984a, 1984b). The homeobox sequences from the *Drosophila Antp* and *Ubx* genes were used in cross-species genomic surveys to identify homeodomain-containing fragments in these animals, and the similarity within the homeodomains was found to be quite high. This conservation across phyla was reinforced by results from subsequent studies, with *HOM-C* homologs found in the genomes of every animal searched. In fact, remarkable conservation is even noted between the *Drosophila HOM-C* genes and their mammalian counterparts despite at least 600 million years of evolutionary separation. For

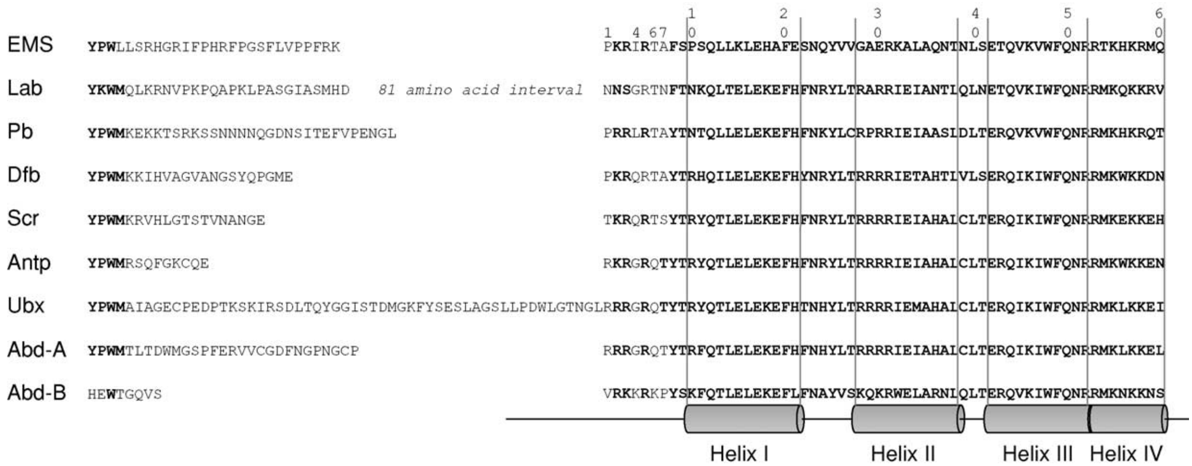

Figure 9 The HOM-C protein homeodomain and YPWM motif. The amino acid sequence of each HOM-C protein and EMS homeodomain, plus a number of residues N-terminal to the homeodomain are aligned to show sequence conservation. Some of the amino acid sequence between the LABIAL homeodomain and YPWM motif is omitted, as 81 amino acids intervene the two conserved domains. Abd-B does not exhibit the conserved YPWM motif, but a conserved tryptophan (W) residue just upstream of the homeodomain may represent the remainder of that motif, and is thus aligned as such. The secondary structure of the homeodomain is shown below the amino acid sequence. Note that α-helices III and IV abut and frequently the homeodomain is considered to have only three α-helices. N-terminal residues key for functional specificity are highlighted and discussed further in the text.

example, *Dfd*, and a mammalian homolog *HOXD-4* (*HOX-4.2*), are conserved within the homeodomain at 55 of 60 residues. *HOXD-4* expression in *Drosophila* is able to activate a *Dfd* responsive reporter in embryos, and produces adult phenotypes similar to those caused by a dominant gain-of-function *Dfd* allele (McGinnis *et al.*, 1990). This level of cross-phylum conservation within the homeobox sequence led Jonathan Slack (1984) to wonder if this conserved sequence could prove to be "the biological equivalent of the slab of basalt found in 1799 near the Egyptian town of Rosetta ... [which] provided the most important clue in the decipherment of the hieroglyphics," and touched off a profusion of study into the homeobox, the homeodomain, and *HOM-C* gene function.

The homeodomain-containing genes of all organisms are classified based on amino acid sequence similarity in and around the homeodomain (Bürglin, 1994). Six of the eight *HOM-C* genes are grouped together as part of the "Antennapedia class" (*pb, Dfd, Scr, Antp, Ubx, abd-A*), and share at least 60% sequence similarity within the homeodomain. The *labial* gene is in a class bearing its name, and its homeodomain is 55–67% similar to members of the *Antp* class. Just upstream from the homeodomain, the *Antp* and *labial* classes share a short conserved motif (the hexapeptide, or YPWM motif), making these classes members of the Hexapeptide superclass of homeobox genes. The Abd-B homeodomain is no more than 55% similar to any other HOM-C homeodomain, diverging significantly in the first two helices of the homeodomain (Celniker *et al.* 1989). The third helix, however, is quite similar, differing from the corresponding *Ubx* region by only a single amino acid. The Abd-B homeodomain does not contain the hexapeptide motif, but does retain a conserved tryptophan residue (W) just upstream of the homeodomain. In the mouse, this residue appears capable of mediating protein interactions similar to those mediated by the hexapeptide motif (Shen *et al.*, 1997). Because its homeodomain sequence diverges significantly from the other HOM-C homeodomains, *Abd-B* is classified separately, in the *Abd-B* class (Bürglin, 1994).

In addition to the *HOM-C* genes, there are numerous other *Drosophila* homeodomain-containing genes. Several are well studied and have provided much of the basis for our understanding of homeodomain structure and function. Particularly well-characterized examples include the segmentation genes *engrailed* (*en*) (Desplan *et al.*, 1985, 1988; Ohkuma *et al.*, 1990; Kissinger *et al.*, 1990; Jaynes and O'Farrell, 1991; Ades and Sauer, 1994; Clarke *et al.*, 1994; Bourbon *et al.*, 1995) and *ftz* (Nelson and Laughon, 1990; Percival-Smith *et al.*, 1990; Florence *et al.*, 1991; Walter *et al.*, 1994), and the maternal factor *bicoid* (*bcd*) (Hanes and Brent, 1989; Treisman *et al.*, 1989; Hanes *et al.*, 1994). All of the HOM-C proteins, and other homeodomain-containing proteins including Even-skipped (Eve), Ftz, and En, have a conserved glutamine (Q) residue at position 50 of the homeodomain and are referred to as the Q50 homeoproteins (Biggin and McGinnis, 1997). Thus, a generalized HOM-C protein can be described as having the following structure: a long N-terminal segment containing the conserved M-repeat/opa-repeat region, a central region, the homeodomain, a short C-terminal region, and a trailer sequence (Desplan *et al.*, 1988). Because the general properties of the homeodomains are quite similar, pertinent data from other homeodomain proteins is useful to fully characterize HOM-C homeodomain structure and function.

1.8.4.2. The HOM-C Homeodomains Bind DNA at a Core Consensus Sequence

The homeodomain sequence was recognized as having features similar to a known transcription factor, the yeast Mat α protein, and to prokaryotic helix–turn–helix repressor proteins (Laughon *et al.*, 1984). It was therefore predicted that the HOM-C proteins might function as DNA binding factors, with the homeodomain as the likely binding motif. Studies undertaken to characterize homeodomain function included genetic interactions, transcription assays, DNA–protein cross-linking assays, immunoprecipitation, and DNA footprinting experiments. The results of this work confirmed the predicted function of the homeodomain as a DNA binding motif and that of the HOM-C proteins as transcriptional regulators (e.g., see Desplan *et al.*, 1985; Müller *et al.*, 1988; Samson *et al.*, 1989; Krasnow *et al.*, 1989; Johnson and Krasnow, 1990, respectively). In fact, it is now known that the homeodomain is one of the most common DNA binding motifs found in eukaryotic transcriptional regulators, second only to the C2H2 zinc finger class (Tupler *et al.*, 2001).

Numerous *in vitro* studies with the HOM-C homeodomains resulted in the characterization of a core consensus DNA recognition sequence. An early study of HOM-C protein/DNA interactions used DNAse protection to characterize the Antp homeodomain (ANTP-HD) recognition sequence. This peptide exhibited specific DNA binding affinity for the sequence 5′-TAATG-3′ (Müller *et al.*, 1988; Affolter *et al.*, 1990; Ekker *et al.*, 1994). The ANTP-HD was also found to form a more stable complex with DNA than did the similarly structured prokaryotic HLH proteins. The extended recognition

helix, formed by helices three and four, may contribute to this increased stabilization. Other studies of HOM-C/DNA interactions involve partial or full-length Dfd, Antp, Ubx, and Abd-B proteins (Desplan *et al.*, 1988; Ekker *et al.*, 1991, 1992, 1994; Wilson *et al.*, 1996). Although Abd-B appears to bind preferentially to a slightly different core sequence of 5′-TTAT-3′ (Ekker *et al.*, 1994), the Q50 homeodomains consistently recognize a consensus core sequence of 5′-TAAT-3′ within characterized recognition sites of 5–9 bp (**Figure 10**).

Structural and genetic studies indicate that the nucleotides flanking the core DNA sequence are important for homeodomain recognition, with one upstream base and two downstream bases being of particular importance (Desplan *et al.*, 1988; Hanes and Brent, 1991). Genetic analysis also indicates the importance of bases several positions downstream of the 5′-TAAT-3′ to homeodomain recognition specificity. Interestingly, *in vitro* studies revealed that a single homeodomain peptide can bind different DNA sequences with similar affinities, and that even divergent homeodomain proteins appear to recognize very similar DNA sequences (Desplan *et al.*, 1988; Hoey and Levine, 1988; Walter *et al.*, 1994; Walter and Biggin, 1996). Ubx and Antp have been shown, *in vitro*, to recognize identical consensus DNA sequences (Ekker *et al.*, 1994). Thus, although the HOM-C proteins recognize and bind specific DNA sequences, it appears that they all recognize the same core sequence, suggesting that there must be additional *in vivo* mechanisms involved in directing their biological patterning specificities.

Figure 10 A schematic view of the homeodomain/DNA complex. The three helices of the homeodomain are shown as purple cylinders and numbered (I, II, III). The DNA helix is represented by ribbons and bars. The bar colors denote base identity: green represents adenine (A), red represents thymine (T), blue represents guanine (G), and yellow represents cytosine (C). The recognition helix (helix III) of the HOM-C homeodomain binds directly to DNA in the major groove, recognizing a core consensus sequence of 5′-TAAT-3′. The C-terminal region of this helix is less stable, and is sometimes referred to as helix IV (Qian *et al.*, 1989). The flexible N-terminal arm makes contact with DNA in the minor groove.

1.8.4.3. Functional Specificity of the HOM-C Homeodomain

Because of the strong amino acid conservation and apparent similarities in target site recognition, several studies have attempted to dissect HOM-C protein homeodomains to identify specific residues critical to their biological function. Several groups approached this problem by constructing chimeric HOM-C proteins (swapping various regions of one HOM-C protein for another), then expressing the chimeras in *Drosophila* embryos and adults to assay developmental outcomes and the effects on target gene expression. Although these types of studies have involved the majority of the HOM-C proteins, we summarize, below, the results of selected swapping studies involving the Ubx homeodomain inserted into the Dfd protein (Kuziora and McGinnis, 1989; Dessain *et al.*, 1992; Lin and McGinnis, 1992), and the Scr homeodomain inserted into the Antp protein (Gibson *et al.*, 1990; Furukubo-Tokunaga *et al.*, 1993).

Substitution of the Ubx homeodomain into an otherwise normal Dfd protein is sufficient to introduce Ubx target regulation, and override normal Dfd activity. Wild-type Dfd can autoregulate its own expression in some cells, binding to defined autoregulatory elements to maintain its transcription (Kuziora and McGinnis, 1988b; Lou *et al.*, 1995). The ectopic activation of wild-type Dfd results in the development of ectopic mouthpart material and maxillary cirri in the trunk segments, and the autoactivation of Dfd outside of its normal domain. Activation of a chimeric heat shock- inducible *Dfd* construct, encoding the Ubx homeodomain in place of the Dfd homeodomain, results in a transformation of the larval head segments toward a thoracic identity, as also results from ectopic Ubx expression (González-Reyes and Morata, 1990). The ectopic activation of *Antp* P1, a known *Ubx* target (Beachy *et al.*, 1988), and the concomitant loss of *Dfd* autoregulation are also observed (Kuziora and McGinnis, 1989). Thus, the Dfd/Ubx chimera, with only the homeodomain region changed, alters the protein function to resemble a wild-type Ubx protein construct.

Further studies mapped the functional specificity of the Ubx homeodomain using a series of chimeric proteins, in which different portions of the Ubx homeodomain were substituted into an otherwise normal Dfd protein construct (Lin and McGinnis, 1992). Each construct was tested for its ability to activate the *Dfd* autoregulatory element and the *Antp* P1 promoter. Constructs retaining the Ubx N-terminal homeodomain region also retain the larval head to thoracic transformation produced by the original Dfd/Ubx construct, and activate ectopic *Antp* P1 transcription. Further, substituting only a few N-terminal Ubx homeodomain residues (numbers 0–9) (**Figure 9**) is sufficient to alter ectopic Dfd function and allow initiation of ectopic *Antp* P1 transcription. A chimera containing the Ubx homeodomain with the N-terminal Dfd homeodomain region fails to activate ectopic *Antp* P1 transcription and loses the ability to induce a head to thorax transformation. Both the N-terminal and C-terminal homeodomain regions are required for full Dfd autoactivation: no autoactivation is possible without the N-terminal Dfd region, and only weak autoactivation is possible with the C-terminal portion absent. In summary, these studies demonstrate that the homeodomain is capable of directing HOM-C protein function, and specifically, the N-terminal homeodomain region alone is sufficient to alter HOM-C protein function. The C-terminal flanking region also contributes to functional specificity.

Others took a similar approach in comparing two ANT-C proteins, Antp and Scr. Gibson *et al.* (1990) used the degree of transformation and target gene transcript accumulation to assess the functional specificity of a series of ectopically expressed, chimeric proteins. The Scr homeodomain was substituted into an otherwise normal Antp protein construct and the chimera was expressed in embryos and adults, utilizing an inducible heat shock promoter. This work determined that functional specificity lies in residues both within and adjacent to the homeodomain, and corroborated results obtained with the Dfd and Ubx studies.

Extending the Scr/Antp study, Furukubo-Tokunaga *et al.* (1993) used the chimeric construct to assess the functional requirement of regions outside of the homeodomain, and to more specifically investigate residues within the homeodomain that confer functional specificity. Interchange of the entire protein region N-terminal to the homeodomain seems only to affect the extent of transformation, or "potentiation," but does not alter the overall function from that of the original chimeric protein. Positions 1, 4, 6, and 7 of the homeodomain (**Figure 9**) are the residues that distinguish the wild-type Antp and Scr homeodomains and prove critical to the functional specificity of the chimeric proteins. By substituting the Antp-specific homeodomain residues into the chimeric Scr/Antp protein (wild-type Antp with the Scr homeodomain), a functional Scr protein is reverted to a functional Antp protein. Thus, substitution of these four amino acids alone is sufficient to determine the functional difference between Antp and Scr. Therefore, functional specificity between the homeodomains of two different ANT-C proteins appears to be determined by only a few critical amino acids within the N-terminal portion of the homeodomain, while residues within the large region N-terminal to the homeodomain direct only the extent of the protein's functional effects. Similar studies involving Ubx and Antp, and Dfd and Abd-B produced similar results (Kuziora and McGinnis, 1991; Chan and Mann, 1993; Zhu and Kuziora, 1996).

As discussed above (see Section 1.8.3.6), the phosphorylation state of two N-terminal homeodomain residues (6 and 7) is critical to Scr function. At position 6 of the homeodomain, Scr has a threonine residue, while Antp has a nonphosphorylatable glutamine residue. The phosphorylation state of this N-terminal homeodomain residue may, at least in part, explain some of the differing functional specificities of the Scr and Antp homeodomains.

1.8.4.4. Homeodomain Structure and the Physical Interaction with DNA

The homeodomain structure is highly conserved, as evidenced by strong sequence conservation and three-dimensional structural analysis. The Antp homeodomain was the first HOM-C homeodomain to be structurally resolved, and is the best characterized with regard to the three-dimensional structure. The structure of the Antp protein, both alone and bound to DNA, was resolved by nuclear magnetic resonance (NMR) spectroscopy and X-ray crystallography, revealing detailed information concerning the *in vitro* physical contacts within the protein–DNA complex. These studies are consistent with the structural characterization of other homeodomain–DNA interactions (Fraenkel *et al*., 1998; Hovde *et al*., 2001). Because of strong sequence similarity between the HOM-C homeodomains, the data and conclusions from these studies can be reasonably applied to the remaining *HOM-C* genes and probably other Q50 homeodomain proteins, as well.

NMR resolution of the Antp homeodomain tertiary structure reveals that the homeodomain forms a globular domain, consisting of four helices (**Figure 9**), three well-defined alpha helices and one less organized fourth helix directly abutting the

third (Billeter *et al.*, 1990). The C-terminal end of the third helix, or recognition helix, is somewhat less stable and, therefore, occasionally characterized as a fourth helix, although the homeodomain is most commonly described as having only three helices. An extended N-terminal arm is evident, upstream of the first helix (Qian *et al.*, 1989).

A number of NMR and X-ray crystallography studies have provided the structural details of homeodomain–DNA interactions (Otting, *et al.*, 1990; Hirsch and Aggarwal, 1995; Wilson *et al.*, 1995; Tucker-Kellogg *et al.*, 1997; Fraenkel *et al.*, 1998; Fraenkel and Pabo, 1998; Hovde *et al.*, 2001). A schematic of the homeodomain–DNA interaction is shown in **Figure 10**. Contact between the homeodomain and DNA occurs at the recognition helix and at amino acid residues flanking helix one. The DNA is contacted within a 7 nucleotide region on both sides of the core binding sequence and all but one contact sites are within the major groove. Overall, contacts are made by the homeodomain across two major grooves of the DNA, with the N-terminal arm (containing four amino acids important for functional specificity, and discussed above) contacting the minor groove.

Further support for the importance of the N-terminal homeodomain residues is provided by the structural study of a truncated Antp peptide lacking the first six amino acids of the homeodomain (Qian *et al.*, 1994). Although its three-dimensional structure is virtually identical to that of the intact homeodomain, the K_d for the truncated peptide bound to DNA was found to be approximately 10-fold less than that of the intact Antp peptide. Thus, the N-terminal homeodomain residues contribute significantly to DNA binding affinity and stability, and perhaps contribute to the motif's ability to stably bind and activate target DNA sequences. Interestingly, inclusion of the conserved hexapeptide (YPWM) motif does not add to the stability of the homeodomain–DNA interaction, nor does it increase the DNA binding specificity (Qian *et al.*, 1992). These results support genetic and later structural studies demonstrating that this highly conserved motif functions in protein–protein interactions, rather than being involved in DNA sequence recognition. The YPWM motif and its function are discussed further in the section that addresses the cooperative interactions between HOM-C proteins and other factors.

In summary, the protein products of the HOM-C genes are DNA binding factors recognizing a consensus sequence with a canonical 5′-TAAT-3′ at its core. It is difficult to reconcile how the HOM-C proteins direct developmental pathways leading to distinct and varying cell morphologies when their target recognition sequences are so similar. For example, it is reasonable to assume that the genetic cascade initiated by one HOM-C protein to pattern a gnathal segment is quite different than the cascade initiated by a different HOM-C protein to pattern an abdominal segment. Yet, we see identical amino acid residues within the recognition (third) helix and the ability of multiple homeodomains to recognize identical sequences. Chimeric studies identify a few N-terminal homeodomain residues as important to developmental function, as transformations in the larval cuticle are observed when these critical residues are altered. Larval denticle patterning may, however, provide limited criteria for assessing functional specificity. Several gnathal HOM-C proteins (Dfd, Scr, and Lab), when ectopically expressed, are sufficient to transform the second and third thoracic denticle belts to a first thoracic identity (Kuziora and McGinnis, 1988b; Zeng *et al.*, 1993; T.C. Kaufman, personal communication), though in normal development, only Scr patterns the first thoracic segment. Thus, the larval denticle pattern, alone, may prove insufficient to evidence altered HOM-C functional specificities. Further, the biological specificity of isoforms of the same HOM-C protein (i.e., Ubx) may not result from differences in target DNA sequence recognition, as the homeodomains are unchanged between isoforms. This seeming incongruence between the specificity of HOM-C protein function and the apparent lack of specificity in DNA target recognition is frequently referred to as the "HOX paradox." It seems likely then, that functional specificity results from spatial and/or temporal differences in expression and differential protein interactions. The N-terminal region of the homeodomain and the highly variable regions outside of the conserved portion of the homeodomain may guide cofactor interactions to direct the developmental specificity brought about by the homeotic selector genes.

1.8.5. Cooperative Interactions between HOM-C Proteins and Other Factors

1.8.5.1. A Case for Cofactors

The results from DNA binding studies in *Drosophila*, investigating the specificity of HOM-C protein target recognition, do not appear to provide the degree of specificity required for developmentally distinct cell fates. As described above (see Section 1.8.4.3), Antp and Ubx recognize identical preferential binding sequences and have overlapping expression

domains, yet have very different biological functions (e.g., *Antp* patterns the wing, where *Ubx* patterns the haltere), implying the need for additional mechanisms or factors to direct their target recognition and resulting biological specificity.

Virtually all Q50 homeodomains bind, with varying affinity, to a consensus core sequence of 5′-TAAT-3′ (Gehring *et al*., 1994), and this motif would be expected to occur, on average, once in approximately every 256 bp of DNA in the *Drosophila* genome. Given the estimates of protein concentrations within nuclei, the homeodomain containing proteins Eve and Ftz (Q50 homeodomains) are estimated to bind to high and medium affinity sites at a density between one monomer per 4 kb of DNA (for weakly bound genes) to five monomers per 1 kb of DNA (for strongly bound genes) (Biggin and McGinnis, 1997). One would expect only a portion of these potential binding sites to be required for spatial and temporal regulation of specific target genes. Thus, the simple presence of a HOM-C protein, bound to DNA, is unlikely to bestow target status to a gene. This is nicely illustrated by studies utilizing the HOM-C protein Dfd and a known Dfd autoregulatory sequence.

Multiples of a small Dfd binding fragment, derived from a Dfd autoactivation enhancer, is sufficient to drive β-galactosidase reporter expression in the maxillary segment of *Drosophila* embryos. However, the loss of an imperfect inverted repeat sequence removes the maxillary reporter expression (Zeng *et al*., 1994), suggesting that other proteins must also bind to this fragment to allow activation of transcription. Further, the Dfd protein binds strongly, *in vitro*, to a tandem repeat of its consensus recognition site, but can only significantly activate transcription of a reporter construct containing this site, when it is accompanied by the constitutive VP16 activation domain (Li *et al*., 1999a). Thus, in spite of strong binding, Dfd alone cannot activate the reporter without the addition of an activation sequence, further indicating a requirement for additional factors. Additionally, the Dfd-VP16 fusion activates ectopic expression of *Scr in vivo*, whereas the wild-type Dfd protein does not regulate *Scr*. This demonstrates that the HOM-C proteins likely bind *in vivo* to sites that do not represent their normal target gene promoters or enhancers.

The presence of cooperatively binding proteins, or cofactors, provides a resolution to the conflict between the lack of binding specificity and developmental precision. Biggin and McGinnis (1997) described two potential models of HOM-C/Co-factor interaction, the co-selective binding model and the widespread binding model. The co-selective model proposes that a cofactor is required to direct HOM-C proteins to the appropriate target gene regulatory sites, while the widespread binding model predicts that HOM-C proteins alone are able to bind to many recognition sites throughout the genome, but are only able to activate transcription in conjunction with appropriate, available cofactors. Cooperative transcriptional control mechanisms, such as those the HOM-C proteins appear to require, are not novel and have been described in other organisms. The yeast homeodomain transcription factors MAT a1 and MAT α2 form cooperative heterodimers, which bind DNA to repress the transcription of haploid-specific mating type genes (Goutte and Johnson, 1993; Mak and Johnson, 1993). The mammalian octamer transcription factors (OCT) also contain a POU class homeodomain, which recognizes an octamer sequence motif. Activation of RNA polymerase II mediated transcription at the octamer binding site requires the heterodimerization of OCT factors (Bürglin, 1994). Yeast also provides an example of a homeodomain/zinc finger interaction between the PHO2 and SWI5 proteins during regulation of the HO endonuclease gene (Brazas and Stillman, 1993).

HOM-C gene cofactors would be expected to have properties fullfilling several genetic and biochemical criteria:

- absence of the cofactors would duplicate full or partial HOM-C loss-of-function phenotypes;
- a cofactor would act in parallel to the HOM-C protein, neither functioning as an upstream regulator, nor as a downstream target (although some regulatory "cross-talk" between the two may be expected);
- HOM-C target gene expression would be reduced or absent in the absence of the cofactor; and
- the cofactor may increase the DNA target specificity and/or the DNA binding affinity of its HOM-C partner.

Several *Drosophila* gene products have been described, which meet many, or all, of these criteria. The homeodomain encoding gene *extradenticle* (*exd*), initially described by Peifer and Weischaus (1990), is the best-characterized HOM-C cofactor. Other genes proposed to encode HOM-C cofactors include *teashirt*, (*tsh*) *disconnected* (*disco*), and the partially redundant *disco-related* (*disco-r*), whose proteins include a zinc finger DNA binding motif; *cap'n'collar* (*cnc*), a member of the bZip family; and two genes encoding putative novel transcription regulators, *lines* (*lin*) and *apontic* (*apt*).

1.8.5.2. Extradenticle is a HOM-C Protein Cofactor

The *extradenticle* gene maps cytogenetically to position 14A5 on the X-chromosome and encodes a 378 amino acid protein required for proper embryonic and adult patterning. The *exd* gene is homologous to the *pbx* group of vertebrate genes (Rauskolb *et al*., 1993) and its protein product is a member of the Pbx class of homeodomain proteins (Bürglin, 1994), which share 95% similarity within their homeodomains and 71% similarity across their entire sequences. The Exd homeodomain diverges from those of the *HOM-C* genes, having three extra residues between the first and second α-helix. Atypical homeodomains of this type are referred to as three amino acid loop extension (TALE) homeodomains. A second conserved domain is the PBC-A domain, through which Exd interacts with a second homeodomain-containing protein, Homothorax (Hth) (Ryoo *et al*., 1999). This interaction is discussed in detail below.

Exd is expressed and packaged into the egg during oogenesis (Rauskolb *et al*., 1993). Loss of maternal and zygotic *exd* expression disrupts embryonic development, even more so than does the loss of zygotic *exd* alone. Maternal Exd protein is uniformly distributed and cytoplasmically localized in early embryogenesis and persists until germ band extension (Aspland and White, 1997). Zygotic transcription initiates thereafter, with transcripts initially found uniformly throughout the embryo, and then being modulated thereafter (Rauskolb *et al*., 1995). The initiation of zygotic *exd* expression is unaltered in *HOM-C* mutants, and conversely, the loss of *exd* expression does not affect the expression of the *HOM-C* genes, indicating that these genes act in parallel developmental pathways (Peifer and Wieschaus, 1990; Rauskolb *et al*., 1995). By germ band contraction, expression of *exd* is lost in abdominal segments 7–10, the remaining Exd protein becomes localized to the nucleus, and this nuclear localization is spatially regulated (Aspland and White, 1997). Expression is also evident in the somatic and visceral mesoderm, the CNS and brain, and the larval imaginal discs (Rauskolb *et al*., 1993; Aspland and White, 1997).

Embryos lacking zygotic Exd function die during late embryogenesis and have defects in overall pattern formation (Peifer and Wieschaus, 1990). Development of some head structures is disrupted, and the thoracic segments are altered, with the second thoracic segment adopting a first thoracic-like denticle pattern, and the third thoracic segment showing characteristics of both the first thoracic and second abdominal segments. The identities of the abdominal segments are transformed to those two to three segments more posterior. For example, the first abdominal segment resembles the third or fourth. No effect is detected in the most posterior segments. Weaker alleles are postembryonic lethals, often forming pharate adults with cuticular defects, and clonal analysis demonstrates that lack of Exd also causes transformation of adult structures (González-Crespo and Morata, 1995; Rauskolb *et al*., 1995). Null *exd* clones result in homeotic transformation of adult head structures, legs, and abdominal segments, resembling the phenotypes observed in some *HOM-C* mutants. Antenna and arista are transformed to leg, while the head capsule is altered to resemble the dorsal thorax or notum. Abdominal clones in the first through fourth segments transform towards the fifth or six abdominal segments. Ubiquitous overexpression of *exd* has no affect on segment identities (Rauskolb *et al*., 1995). Because *exd* mutants appeared to have alterations in HOM-C target specificity, Peifer and Wieschaus proposed that Exd acts as a HOM-C cofactor.

Exd homologs have been identified in the cricket *Gryllus bimaculatus*, the cricket *A. domesticus*, the pine sawfly *Diprion similis*, and the grasshopper *S. americana* (Abzhanov and Kaufman, 2000; Jockusch *et al*., 2000; Suzuki and Palopoli, 2001; Inoue *et al*., 2002). These studies examined Exd expression as it is involved in leg development, and found that like *Drosophila*, nuclear Exd is present in the proximal developing leg. There are currently no published data assessing the function of Exd with the HOM-C proteins of other insects. However, the highly conserved nature of the interacting regions of these proteins across several animal taxa (Rauskolb *et al*., 1993; Pöpperl *et al*., 1995; Liu and Fire, 2000) leads us to expect that the protein serves a similarly conserved role across insect taxa. This, however, remains to be demonstrated.

To explore the interaction and contribution of the HOM-C proteins and Exd to development, embryos mutant for *exd* were compared to embryos singly mutant for various *HOM-C* genes and doubly mutant for both a *HOM-C* gene and *exd*. Double mutants differed from either single mutant, indicating that the *HOM-C* genes continued to be active within their normal domains in the absence of *exd*, although they were unable to specify segmental identity properly (Peifer and Wieschaus, 1990). For example, single *exd* mutants exhibit a transformation of the first abdominal segment to the third, the second abdominal segment to the fourth, and the third abdominal segment to the fifth. An *abd-A*

mutant exhibits a transformation of these same segments to an A1 identity. The double *exd;abd-A* mutant transforms all of these segments to an A3 identity. These results further indicate that *exd* functions in a parallel pathway to the *HOM-C* genes and is required for the normal specification of segment identity by the *HOM-C* genes examined.

Consistent with the expectation of some cross-regulation between the HOM-C proteins and their cofactors, late stage *exd* expression is modulated by HOM-C proteins (Rauskolb *et al*., 1993). Embryos deficient for the *BX-C* genes have increased posterior expression of *exd* late in embryogenesis, indicating the BX-C proteins downregulate *exd* expression in the posterior abdomen. Further, Ubx, Abd-A, and Abd-B modulate the subcellular localization of Exd protein, albeit to different extents (Azpiazu and Morata, 1998).

Genetic and biochemical studies support a cooperative transcriptional activation by a HOM-C/Exd heterodimer. The *HOM-C* genes *Ubx*, *abd-A*, and *Antp* are required for normal midgut development and directly modulate the expression of genes within this developing tissue, including *wingless* (*wg*), *teashirt* (*tsh*), and *decapentaplegic* (*dpp*) (Immerglück *et al*., 1990; Reuter *et al*., 1990). The regulation of *wg* expression within the visceral mesoderm of parasegment 8 is controlled by Abd-A, and Antp positively regulates *tsh* within the visceral mesoderm of parasegments 5 and 6. Expression of *wg* and *tsh* is lost in these regions when embryos lack Exd, although there is no alteration of the expression of either Abd-A or Antp (Rauskolb and Wieschaus, 1994). The requirement of Exd for proper HOM-C protein function is illustrated again with Ubx. The *dpp* gene, a member of the transforming growth factor (TGF)-β-encoding gene super family, is a direct target of Ubx *in vivo* and is also required for midgut morphogenesis (Capovilla *et al*., 1994; Chan *et al*., 1994). Ubx directly activates the transcription of a *dpp* minimal enhancer construct in parasegment 7 within the visceral mesoderm, and this region-specific activation requires Exd (Rauskolb and Wieschaus, 1994; Sun *et al*., 1995). Even the ectopic expression of Ubx in embryos lacking Exd fails to activate the *dpp* enhancer element.

Exd is also required for epidermal function of the *HOM-C* gene products. Removing both maternal and zygotic Exd appears to abolish Dfd function, as the mandibular and maxillary derived larval structures are eliminated (Peifer and Wieschaus, 1990). Further, some Dfd response elements require Exd to emulate normal expression *in vivo* (Pinsonneault *et al*., 1997). Unlike Antp, Abd-A, and Ubx, however, Dfd expression is severely reduced when both maternal and zygotic Exd are removed. Although initially normal, Dfd protein accumulation dramatically decreases during the germ band stage, the time at which Dfd begins to maintain its own transcription through autoactivation. Therefore, it appears that Exd is necessary for Dfd autoactivation. Similarly, Lab requires Exd for maintenance of its own expression *via* an autoactivation circuit (Chan *et al*., 1996), and Ubx requires Exd for transcription maintenance in the haltere imaginal discs (Azpiazu and Morata, 1998). It is suggested that Exd may not only cooperatively activate transcription by the HOM-C proteins, but may also alleviate the repressive action of some bound HOM-C factors (Pinsonneault *et al*., 1997; Li *et al*., 1999b) or even promote the repressive properties of HOM-C proteins (Ryoo and Mann, 1999; Merabet *et al*., 2003).

The evidence supporting Exd/HOM-C interactions is not only based on results from genetic studies. *In vitro* binding studies demonstrate that the Exd and HOM-C proteins interact directly and can bind DNA cooperatively with greater affinity than the HOM-C proteins alone (van Dijk and Murre, 1994; Chan and Mann, 1996; Pinsonneault *et al*., 1997; Ryoo and Mann, 1999). Exd can also selectively enhance the specific affinity of one HOM-C protein relative to others for binding to a particular target region. Scr and Exd bind a response element derived from the Scr target gene *fork head* (*fkh*) cooperatively and specifically (Ryoo and Mann, 1999). The Exd/Scr heterodimer binds effectively to this element *in vitro*, and both proteins are required for the activatation of a reporter construct carrying this element *in vivo*. Other Exd/HOM-C heterodimers fail to activate this element *in vivo* and fail to bind to it with high affinity *in vitro*, while Exd is unable to bind the element alone. Two half-sites are required for the Exd/HOM-C heterodimer to bind DNA, one recognized by the HOM-C protein homeodomain, and one recognized by the Exd homeodomain (van Dijk and Murre, 1994). Although these sites vary slightly for different heterodimers, a consensus sequence of 5′-ATNNATCA-3′ has been described (Mann and Chan, 1996).

The ability of the Exd mammalian homologue Pbx to bind cooperatively with mammalian HOX proteins and some of their *Drosophila* homologs *in vitro* and *in vivo*, illustrates the level of conservation of the Exd/PXB family (Chan *et al*., 1994; van Dijk and Murre, 1994; Chang *et al*., 1995; Phelan *et al*., 1995; Pöpperl *et al*., 1995; Rauskolb and Wieschaus, 1994; Sun *et al*., 1995; Chang *et al*.,

1997; Azpiazu and Morata, 1998). This strong conservation across phyla, combined with the similar interactions between the yeast factors MATa1 and MATα2, suggests that the Exd/HOM-C(HOX) interaction could be quite ancient, dating back to the earliest origins of multicellularity.

1.8.5.3. The DNA Bound Exd/Ubx Crystal Structure

Chan and Mann (1996) used a series of point mutations to characterize the Exd/Lab/DNA interaction, and proposed a structural model for HOM-C/Exd interactions, much of which was later confirmed by structural resolution. X-ray crystallography was used to resolve the crystal structure of a DNA-bound Ubx/Exd heterodimer (Passner *et al*., 1999).

The Ubx and Exd homeodomains bind opposite faces of the DNA molecule, aligned in a head to tail orientation in close proximity (**Figure 11a**). As indicated by *in vitro* and *in vivo* data, the HOM-C hexapeptide or YPWM motif and the Exd homeodomain are the sites of protein–protein interaction. Able to form a reverse turn, the YPWM motif extends, via a flexible linker, to contact Exd within a hydrophobic pocket (**Figure 11b**). This pocket is formed, in part, by the additional three residues between alpha helices 1 and 2 of the Exd homeodomain. The tryptophan (W) residue is significant to Exd/Ubx binding, mediating hydrophobic contacts within the Exd hydrophobic pocket. The contacts made by the tyrosine (Y), proline (P), and methionine (M) residues are less extensive and serve to stabilize the binding of the tryptophan (W) residue. The proximity of the two proteins results in highly overlapping binding sites, with more than half of the Exd contacts to DNA occurring within the Ubx recognition site. The binding of the Exd/Ubx dimer to DNA induces very little conformational change in the proteins, however the minor groove of the bound DNA region broadens significantly, when compared to the crystal structure of Antp bound to DNA complex (Fraenkel and Pabo, 1998). This broadening may represent a "preconfiguring" of the DNA by Exd to allow Ubx recruitment to its target site. A similar mechanism of cooperative binding has been suggested for Oct1 (Clemm and Pabo, 1996).

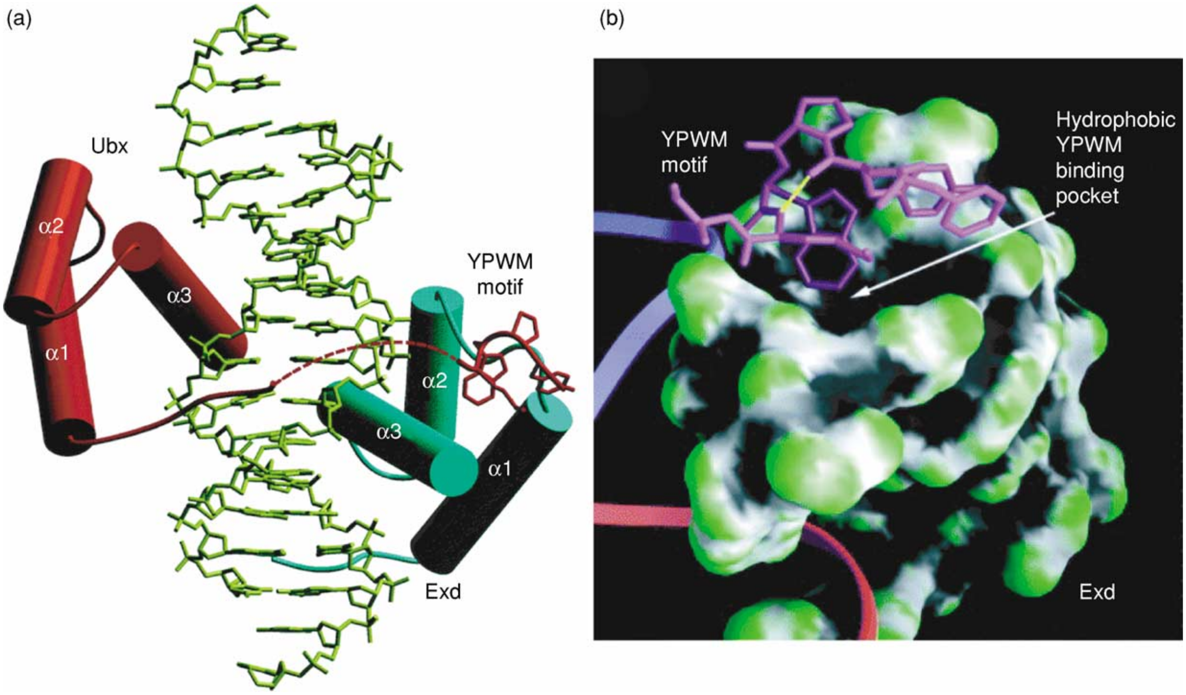

Figure 11 The Ubx/Exd/DNA ternary complex. (a) The Ubx/Exd complex binding DNA and (b) Ubx/Exd protein–protein interaction. (a) The diagram shows the Ubx (red) and Exd (green) homeodomains binding cooperatively on opposite faces of the DNA (green). The flexible linker between the Ubx homeodomain and its YPWM motif is represented by a dashed red line. (b) The YPWM motif (magenta) of Ubx forms a reverse curve to reach into a hydrophobic pocket on the Exd homeodomain. The yellow line indicates a hydrogen bond between the first and fourth residues of YPWM. The colored surface of Exd illustrates its curvature: convex patches are shaded green and concave patches are shaded gray. The DNA backbone (purple and red) is shown as a reference. (Adapted with permission from Nature Publishing Group from Passner, J.M., Ryoo, H.D., Shen, L., Mann, R.S., Aggarwal, A. **1999**. Structure of a DNA-bound Ultrabithorax–Extradenticle homeodomain complex. *Nature 397*, 714–719; http://www.nature.com/nature/)

1.8.5.4. The YPWM (Hexapeptide) Motif and Exd/HOM-C Heterodimer Formation

Variously called the hexapeptide motif, the pentapeptide motif, the tetrapeptide motif, and the YPWM motif, this short, highly conserved region N-terminal to the HOM-C homeodomain is integral to the Exd/HOM-C interaction (Chan and Mann, 1996) (**Figure 9**). Yeast two-hybrid, mutational, and structural analyses reveal that the region of interaction between Pbx/Exd and its HOX/HOM-C partners is the conserved YPWM motif (Chang *et al*., 1995; Johnson *et al*., 1995; Phelan *et al*., 1995). NMR studies involving the highly conserved vertebrate Pbx homeodomain, describe a "lock and key" interaction, with the YPWM motif of the HOX protein (key) inserting into the hydrophobic pocket (lock) of the Pbx homeodomain (Sprules *et al*., 2003).

Despite the apparent genetic and structural importance of the YPWM motif for Exd/HOM-C interaction and DNA binding, however, there are also examples of its dispensability. Abd-B, which lacks this conserved motif, fails to cooperatively interact *in vitro* with Exd (van Dijk and Murre, 1994), although a murine Abd-B homolog does appear to be able to interact with Pbx, despite the lack of the YPWM sequence (Izpisua-Belmonte *et al*., 1991). Recent work with Abd-A demonstrates that the YPWM motif is neither required for Exd recruitment, nor for DNA binding and target selection (Merabet *et al*., 2003). Elimination of the YPWM motif, or a second, short conserved linker-region sequence, does not affect Abd-A's epidermal patterning functions, its binding site selection on a *dpp* response element, or its ability to interact with Exd and Hth *in vitro*. The sequence was, however, proven to be required for correct regulation of the Abd-A target genes *wg* and *dpp* within the visceral mesoderm, where the YPWM motif confers both target activating and target repressing properties to Abd-A, in a gene-specific manner. The *wg* and *dpp* genes are differentially affected by the loss of the YPWM motif, demonstrating the importance of this motif in the control of Abd-A *trans*-regulatory functions.

1.8.5.5. Homothorax Forms a Trimer with Exd and HOM-C Proteins

In order for Exd to function as a coregulator of the HOM-C proteins, it must move from the cytoplasm into the nucleus. Interestingly, Exd has no nuclear localization signal (NLS), but relies on yet another homeodomain-containing protein, Homothorax (Hth), to translocate to the nucleus (Rieckhof *et al*., 1997; Ryoo *et al*., 1999). This relationship is also conserved among the vertebrate Pbx proteins, which require interaction with Hth homologs, the MEIS (named after the founding member, myeloid ecotropic viral integration site 1 or MEIS1; Moscow *et al*., 1995) proteins, for nuclear localization (Knoepfler *et al*., 1997). The absence of *hth* in embryos results in posterior-directed transformations, just as observed with embryos lacking *exd*. Hth has a conserved N-terminal domain, the HM (*hth/meis*) motif, which binds Exd at the PBC-A domain, allowing the formation of a trimeric Hth/Exd/HOM-C (Ryoo *et al*., 1999). This binding structure leaves the Hth homeodomain available to interact with DNA, perhaps further increasing the specificity of the Exd/HOM-C interaction. A trimeric Hth/Exd/Lab complex was shown to bind DNA at an endodermal *lab* autoregulatory enhancer (*lab48/95*). Hth is required for the *in vivo* function of a *lac-Z* reporter construct containing this enhancer, while ectopic expression of a form of Hth lacking the homeodomain acts in a dominant negative fashion, nearly abolishing reporter activity (Ryoo *et al*., 1999). DNA footprinting analysis of an Hth/Exd/Lab/DNA complex indicates that Hth binds approximately 12 bases away from the overlapping Exd/Lab binding site, and that high-affinity Hth binding requires the Exd/Lab binding as well. Lab and Hth do not bind DNA cooperatively in the absence of Exd.

1.8.5.6. Extradenticle Is Insufficient to Fully Explain HOM-C Function

An interesting series of studies illustrates the difficulties in interpreting and correlating *in vitro* binding results with *in vivo* function, particularly when examining minimal response elements. The *HOXB-1* gene is a vertebrate homolog of the *Drosophila lab* gene. A well-characterized 20 bp *HOXB-1* element (derived from the 5′ *HOXB-1* promoter) is bound cooperatively and specifically by Exd and Lab and is able to recapitulate endogenous *lab* expression patterns in *Drosophila* embryos (Pöpperl *et al*., 1995; Chan *et al*., 1996). The *in vivo* function of this reporter requires both Exd and Lab. The consensus Exd/HOM-C recognition site has been described as 5′-ATNNATCA-3′ (Mann and Chan, 1996). A change in the two central base pairs (the NN "specificity residues") of the consensus Exd/HOM-C binding site, from GG to TA, alters the *in vitro* specificity from Exd/Lab, to Exd/Dfd and results in strong *in vivo* reporter expression in a Dfd-like pattern (Chan *et al*., 1997). At first glance, it appears that a simple change in a few base pairs is sufficient to direct *in vivo* HOM-C specificity, but

further studies have shown, that, although Exd/Ubx also binds the altered 20 bp *HOXB-1* response element *in vitro*, it is unable to activate this element *in vivo* (Chan and Mann, 1996; Chan *et al.*, 1997). Additional, difficult to interpret results involve a 26 bp element from the regulatory region of the *Drosophila* gene *Distal-less* (*Dll*), an element negatively regulated by Ubx and Abd-A, and bound by both HOM-C proteins at the same site (White *et al.*, 2000). This element was altered to resemble the known Exd/Dfd consensus sequence, and placed into a reporter construct. Interestingly, while the altered *Dll* element continued to be negatively regulated by Ubx and Abd-A, it was strongly activated by Scr and only weakly activated by Dfd. Further, Li *et al.* (1999a) demonstrated that an Exd/Lab responsive element could be altered to a Dfd responsive element by the addition of a naturally derived 21 bp region that included neither an Exd/HOM-C binding site nor a Dfd binding site. Results such as these serve to reinforce the complexity of the Exd/HOM-C protein mechanism of target recognition. Obviously, a simple consensus sequence with two variable nucleotides cannot fully explain the complex action of these genes.

Although Exd certainly functions as a coregulator with HOM-C proteins, it is clear that Exd alone does not define HOM-C target specificity. Not all Dfd response elements require Exd for *in vivo* function, suggesting there are multiple regulatory mechanisms at work for a single HOM-C protein (Pederson *et al.*, 2000). *In vitro* binding studies demonstrate the ability for multiple Exd/HOM-C heterodimers to bind similar sequences (i.e., with Ubx and Abd-A), suggesting that Exd alone cannot explain the functional specificity of the HOM-C proteins (van Dijk and Murre, 1994). Abd-B appears necessary to repress *exd* activation, rather than utilize it as a cofactor, and Pb represses *exd* expression during the development of the adult proboscis (Abzhanov *et al.*, 2001). Further, in the case of Scr, which is expressed in both the head (labial segment) and the trunk (first thoracic segment), coregulation with Exd is insufficient to explain this HOM-C protein's ability to differentially pattern segments from two different tagmata, suggesting that other cooperative factors must be at work. In fact, cooperative interactions between HOM-C proteins and a cofactor may not be limited to Exd. Several other DNA binding proteins appear to coregulate HOM-C function, but in a more region-specific manner than the coregulation observed with Exd. Direct interaction between these factors and a HOM-C protein, however, has yet to be demonstrated.

1.8.5.7. Zinc Finger HOM-C Protein Cofactors

Several other *Drosophila* proteins are proposed to function as HOM-C cofactors, including the C2H2 zinc finger proteins encoded by *tsh*, *disco*, and the partially redundant *disco-r* genes, and perhaps the *buttonhead* (*btd*) gene. Of these, *tsh*, located on the left arm of chromosome 2, is well characterized in *Drosophila*, while some information is also available from other insects. The *tsh* gene was initially identified in an enhancer trap screen for embryonic segmentation genes (Fasano *et al.*, 1991). Embryos homozygous for null alleles of *tsh* die before hatching, and have a homeotic alteration of the ventral trunk segments to a gnathal- or head-like structure. The denticle belts are reduced, laterally narrowed, disorganized, and lack segment-specific characteristics. Small patches of sclerotized material, reminiscent of the cephalopharyngeal skeleton, are present in the ventral cuticle, and the anal opening is also sclerotized. The expression of *tsh* overlaps expression of *Scr*, *Antp*, *Ubx*, *abd-A*, and *Abd-B*, but is not required for transcriptional activation of these genes (Röder *et al.*, 1992). Conversely, initiation and early regulation of *tsh* is independent of the HOM-C proteins, although Antp, Ubx, and Abd-A modulate *tsh* expression later, following germ band extension (Mathies *et al.*, 1994; McCormick *et al.*, 1995). The expression of *Scr* is somewhat affected by the loss of *tsh*, exhibiting ectopic activation in the ventral prothoracic segment (Fasano *et al.*, 1991). Röder *et al.* (1992) concluded that *tsh* acts on the same hierarchical level as the *HOM-C* genes, with the two functioning together to promote proper trunk development while suppressing head identity. The *tsh* mutant phenotype and its expression in all of the trunk segments except for the most posterior abdominal, has led to its characterization as a trunk tagma specifier.

Further work by de Zulueta *et al.* (1994), supports a cooperative mechanism between *tsh* and the *HOM-C* genes of the trunk. The role of Tsh during development is highlighted by its connection with the *HOM-C* gene *Scr.* As discussed previously (see Section 1.8.2.2.4), Scr controls identity in the labial gnathal segment and in the adjoining first thoracic trunk segment. Part of this dual role is specified by *tsh*. Scr is unable to produce a first thoracic identity in the absence of *tsh*, as evidenced by the failure of *tsh* null embryos to differentiate normal first thoracic denticle belts. Ectopic activation of *tsh* in the labial segment transforms that segment toward a prothoracic identity with first thoracic-type denticles. Tsh is also required for repression of salivary gland formation in the trunk segments in embryos

ectopically expressing Scr, again demonstrating that Tsh helps to distinguish the gnathal versus the trunk roles of Scr (Andrew *et al.*, 1994).

Embryos null for the partially redundant genes *disco* and *disco-r* exhibit gnathal patterning defects quite similar to those observed in embryos lacking Dfd and Scr (Mahaffey *et al.*, 2001). These genes map to the 14B1 and 14A9 regions, respectively, of the X chromosome and encode paired zinc finger-containing proteins. Although *disco* had been previously characterized based upon neural and circadian rhythm phenotypes (Steller *et al.*, 1987; Dushay *et al.*, 1989; Helig *et al.*, 1991), its embryonic patterning role remained unrecognized until the creation of a deficiency removing both *disco* and *disco-r*; either gene alone is sufficient for normal embryonic gnathal patterning (Mahaffey *et al.*, 2001). The expression of *disco* and *disco-r* overlaps that of *Dfd* and *Scr* in the mandibular, maxillary, and labial lobes, and the former are also expressed in the larval limb primordia of the first through third thoracic segments and the clypeolabrum. In addition, *disco* is expressed in the optic lobe, where it is required for normal migration of Bolwig's nerve, and in the proctodeum, where it overlaps with *Abd-B* expression. Loss of *disco* and *disco-r* has no effect on the expression of *Dfd* or *Scr*, and the converse loss of *Dfd* and *Scr* has no significant effect on the expression of the *disco* or *disco-r* genes (Mahaffey *et al.*, 2001), further demonstrating that *disco/disco-r* null embryos exhibit reduced expression of three known Dfd target genes–*1.28*, *Serrate* (*Ser*), and *Dll*–and supporting the role of these two proteins as HOM-C cofactors.

The *btd* gene also encodes a zinc finger transcription factor required for embryonic patterning (Wimmer *et al.*, 1993). Mutations in *btd* disrupt development of the anterior head segments, including the antennal, intercalary and mandibular segments. The Btd protein interacts with and functions as a cofactor with the HOM-C-like protein, Empty Spiracles (EMS) (Dalton *et al.*, 1989), and overlaps the expression of Lab and perhaps Dfd. *ems* is a *HOM-C* like gene required for pattering the *Drosophila* larval head and brain, and for the development of the filzkörper material in the posterior spiracles (Dalton *et al.*, 1989; Jones and McGinnis, 1993). Although commonly referred to as a head gap gene (Cohen and Jürgens, 1990; Walldorf and Gehring, 1992), *ems* encodes a *HOM-C* type homeodomain and a somewhat diverged upstream YPWM motif (**Figure 9**). It has been suggested that *ems* may represent a "lost" *HOM-C* gene, separated from the *HOM-C* cluster, but retaining *HOM-C* like patterning functions (Macías and Morata, 1996). Interestingly, ectopic *ems* expression causes little disruption to development, only transforming the mandibular segment toward an intercalary identity. Ectopic *btd* expression, on the other hand, is more detrimental, causing segmentation defects. However, ectopic expression of *ems* with *btd* appears to transform the trunk segments toward an intercalary identity, demonstrating that the region of Btd accumulation defines where EMS can function, much as would be expected for a cofactor (Schöck *et al.*, 2000). This property is similar to the observations of HOM-C proteins with Tsh and Disco.

There are few studies with homologs of these zinc finger cofactors in other insects, yet this could be a very interesting and informative venture. Unlike the *HOM-C* genes, there appear to be differences in these putative zinc finger cofactors between *Drosophila* and other insects. Somewhat surprisingly, all of the zinc finger genes mentioned above have been duplicated in the *Drosophila* genome (the *Drosophila* homolog of mammalian SP1 (Kadonaga *et al.*, 1987); *tsh* is related to *tiptop*, and *btd* is related to *D-Sp1*), and *disco*'s duplicate, *disco-r* has already been mentioned above. Only *disco* and *disco-r* have been shown to be functionally redundant for their role with HOM-C proteins. The *D-Sp1* gene can substitute for *btd* in the mandibular segment (Schöck *et al.*, 2000), but little is know about the role of *tiptop*.

With several insect genome projects well under way, it is clear now that these duplications are not found in all insects. In the genomes of *A. gambiae* and *A. mellifera* only homologs of *disco-r* and *tiptop* are found. Further, a search of Genbank reveals several homologs of *tsh* cloned from other insects, and although many of these are only partial sequences, they appear to be more closely related to *tiptop* than to *teashirt*. This generates several questions. Since only *disco* and *disco-r* appear to be redundant, what are the roles of the paralogous genes in *Drosophila*, and further, what roles will be found for the genes in other insects? For example, will *tiptop* from other insects retain the roles of *tsh* and *tiptop* in *Drosophila*? Additionally, it will be important to determine which roles are ancestral and which are derived, whether or not the cofactor role for these genes is particular to *Drosophila* or whether it extends to other insects as well.

Recently, Robertson *et al.* (2004) proposed a model in which the C2H2 zinc finger transcription factors described above play a larger role during *Drosophila* development and HOM-C function. In this model, these transcription factors contribute to the regionalization of the embryo: Disco establishing the gnathal region and Tsh the trunk (**Figure 12**). Btd may have a similar role in the anterior head, as we

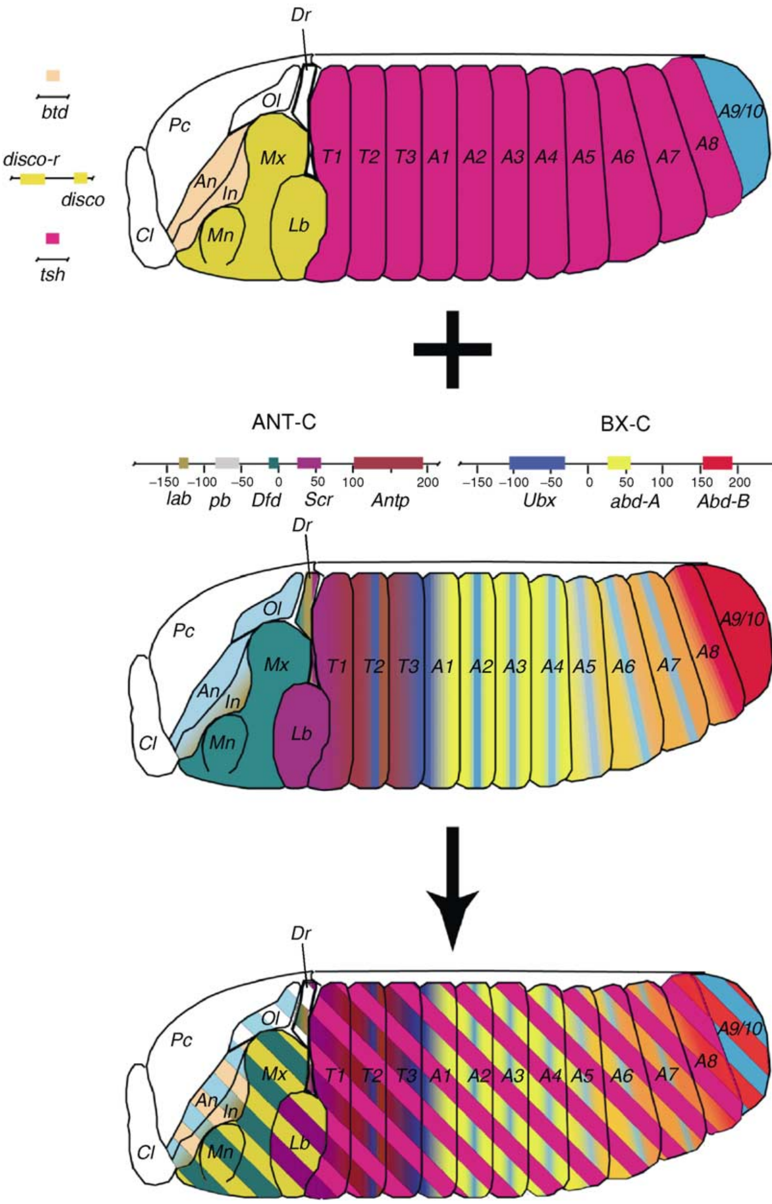

Figure 12 A model for regional specification and establishment of HOM-C protein function. The regionally expressed zinc finger transcription factors (upper image) participate in the regionalization of the *Drosophila* embryo. Some details of the expression patterns and function were intentionally left out for clarity. The anterior head region is postulated to be controlled by *btd*, the gnathal region by *disco* and *disco-r*, and the trunk region by *tsh*. At present, the identity of a similar posterior abdominal factor is not known, although there are several candidates. A gene map and diagram representing the domains of *HOM-C* gene expression and control are shown in the middle. These expression patterns are described in the text. Finally, in the lower panel, the two gene expression patterns are merged and the zinc finger expression patterns are represented by the angular views through the HOM-C expression pattern. Unique combinations of C2H2 zinc finger transcription factors and HOM-C proteins in each segment specify individual segment identities.

have suggested in Figure 12. These authors have shown that this is an interactive network, where the Tsh protein can repress expression of the *disco* genes, restricting *disco* and *disco-r* expression to the gnathal region. In the absence of Tsh, *disco* and *disco-r* are ectopically expressed in the trunk segments, which appears to be responsible for the trunk to gnathal transformation seen in homozygous *tsh* mutant embryos. In addition to this regionalization role, these zinc finger proteins participate with the HOM-C proteins during the establishment of the anterior–posterior axial pattern of

the *Drosophila* embryo. Robertson *et al.* (2004) show that *disco* expression establishes the regions where cells can respond to Dfd and Scr proteins. When embryos lack *disco* and *disco-r*, they do not respond to ectopic activation of these *HOM-C* genes, neither by activating gnathal HOM-C target genes nor by producing ectopic mouthpart structures, as do embryos expressing Disco (either endogenously or ectopically).

The picture now emerging is one in which the C2H2 zinc finger proteins help regionalize the embryo and define domains, in which specific HOM-C proteins can function. This does leave several important questions that need to be resolved. For example, are these zinc finger proteins biochemical cofactors for the HOM-C proteins? In addition, it is not known if the zinc finger proteins have the same HOM-C partners during adult development as they do during embryogenesis, and further, it is not clear whether or not this mechanism is functioning in other insects (see below). Indeed, this may be a crucial question, since there are indications that the relative expression of these zinc finger genes may be conserved in vertebrates, suggesting that function may be conserved as well. In either case, this opens a new avenue of study for the function of insect HOM-C proteins.

Although little is currently known regarding the role of related zinc finger proteins in other insects, expression of a homolog of *tsh/tiptop* (*Tdtsh*) has been examined in *Thermobia*, and some information may be inferred regarding *Tribolium*. Expression analysis for *Tdtsh* reveals a pattern altered from that observed in the fly, with *Tdtsh* being expressed primarily in the thoracic and ventral gnathal segments, with only weak expression visible in the abdominal segments (Peterson *et al.*, 1999). Peterson *et al.* (1999) suggest that *Tdtsh* may specify the thoracic tagmata in *Thermobia*, rather than the larger trunk region as proposed for the *Drosophila* larva. The gnathal expression in *Thermobia* embryos may reflect *tsh*'s role in adult *Drosophila* head patterning, where it is required to suppress the activity of *Antp* (Bhojwani *et al.*, 1997). *Tribolium* embryos lacking the *HOM-C* genes differentiate antennae in each thoracic and abdominal segment (Peterson *et al.*, 1999, Brown *et al.*, 2002b), indicating that *tsh* may not act to specify the trunk tagmata as in *Drosophila*. It is unclear, however, whether the trunk to head transformation observed in *Tribolium* is limited to the appendages, or applies to an entire segment. Thus, *tsh* may retain a role as a HOM-C cofactor in a more basal insect species, but further work is needed to determine if this is the case.

1.8.5.8. Other Potential HOM-C Protein Cofactors

The proteins encoded by *cap 'n'collar* (*cnc*), *lines* (*lin*), and *apontic* (*apt*) have also been suggested as putative HOM-C protein cofactors. The *cnc* gene, located on the right arm of chromosome 3, encodes a member of the bZip protein family and produces three protein isoforms (A, B, and C) ranging in size from 533 to 1296 amino acids (McGinnis *et al.*, 1998). Its activity is required for normal patterning of the embryonic mandibular and labral segments. Loss of *cnc* function causes a transformation of the mandibular lobe towards to a maxillary identity, demonstrated by the formation of ectopic mandibular mouth hooks and cirri (Mohler *et al.*, 1995). The CNC isoform B (CNC-B) localizes to the mandibular and labral segments, overlapping with Dfd expression in the mandibular segment. In contrast to the role of *disco* and *disco-r*, which appear necessary for Dfd activation of target genes, normal CNC-B function diminishes the activity of Dfd response elements by antagonizing the *Dfd* autoregulatory pathway. Mutants of *cnc* have persistent Dfd accumulation in the anterior mandibular lobe (where Dfd protein levels decrease in wild-type embryos during germ band contraction), and the overexpression of *cnc* during embryonic development produces a phenotype very similar to that of null *Dfd* embryos (McGinnis *et al.*, 1998). Taken together, these results support the cospecification of mandibular identity by CNC and Dfd. The gnathal pattern of *cnc* expression is very similar in *Thermobia* and *Oncopeltus*, thus the *cnc* homologs in these insects may be functioning in a similar way to *Drosophila* (Rogers *et al.*, 2002).

The putative HOM-C cofactor encoded by *apontic* (*apt*) was identified in a second chromosome screen for modifiers of Dfd function (Gellon *et al.*, 1997). Embryos mutant for *apt* share some phenotypic characteristics with both *Dfd* and *Scr* mutant embryos, including the extreme reduction of the dorsal pouch and the loss of the dorsal bridge. Other cephalopharyngeal structures lost in *Dfd* and *Scr* mutant embryos are, however, retained in *apt* mutants. Zygotic a*pt* transcripts localize to the dorsal acron, clypeo-labrum, and ventral and anteriolateral gnathal lobes. A segmentally repeated pattern is observed in the trunk epidermis and CNS. Because loss of *apt* has no apparent effect on *Dfd* and *Scr* transcription, and these *HOM-C* genes do not affect the transcription of *apt*, these genes likely function in parallel to pattern portions of the gnathal region. Like *disco* and *disco-r*, *apt* does not

affect the *Dfd* autoregulatory loop, and thus may directly coregulate some Dfd target genes.

Another region of embryonic *apt* expression includes the developing dorsal vessel and heart, and *apt* is required for appropriate heart morphogenesis and function (Su *et al*., 1999) (see **Chapter 2.6**). The homeotic proteins Antp, Ubx, and Abd-A determine the anterior–posterior portioning of the dorsal vessel into the aorta and heart, and Abd-B represses cardiogenesis (Lo *et al*., 2002; Lovato *et al*., 2002). An interesting question is whether APT might also function in concert with one or more of these HOM-C proteins in the development of the larval circulatory system.

In the eighth abdominal segment, identity is primarily controlled by the *HOM-C* gene *Abd-B*, and requires the activity of the Abd-B target genes, *empty spiracles* (*ems*), *spalt major* (*salm*), and *cut* (*ct*). The segment polarity gene *lines* (*lin*) (Volk *et al*., 1994; Bokor and DiNardo, 1996) is also required for the proper patterning of the posteriormost abdomen and may function as a cofactor for Abd-B in this domain. Expression of Abd-B is normal in *lin* mutants (Castelli-Gair, 1998), but the posteriormost segment fails to develop normally and lacks posterior spiracles, mirroring a phenotypic effect of the loss of Abd-B function (Sánchez-Herrero *et al*., 1985). The LIN protein appears to function cooperatively with Abd-B in the transcriptional activation of an *ems* reporter construct and both *salm* and *ct*. Another function of Abd-B is the repression of the more anterior *BX-C* genes, *Ubx* and *abd-A* (Struhl and White, 1985; Macías *et al*., 1990). Gene *lin* mutants have no effect upon the expression of these *HOM-C* genes, indicating Abd-B does not require LIN for this repressive function. Current information indicates that LIN only coregulates Abd-B targets, as there is no evidence of alteration in Abd-A, Ubx, or Dfd downstream target expression. As Abd-B appears not to require Exd as a cofactor, *lin* is currently the only gene known to produce a putative Abd-B transcriptional coregulator.

1.8.5.9. HOM-C Protein Function in the Absence of Cofactors: Cooperative Binding

There is much evidence to support that HOM-C proteins function while interacting with cofactors, but is there evidence that target gene regulation can occur without cofactors? Some *Drosophila* promoter and enhancer regions contain clustered recognition sites for a single transcription factor (for examples, see Laughon *et al*., 1988; Yang *et al*., 2001; Markstein *et al*., 2002), and *in vitro* studies demonstrate that homeodomain proteins can bind cooperatively to clustered sites (Desplan *et al*., 1988). Such clustering may provide the means for spatially and temporally specific gene activation based on the concentration of a given factor(s). A mechanism such as this may provide some explanation for the biological specificity directed by the *HOM-C* genes, in spite of their overlapping DNA binding specificities. Indeed, this type of transcriptional regulation was shown to be true for other early-acting patterning genes (reviews: Pankratz and Jaeckle, 1990; Small and Levine, 1991; St Johnston and Nüsslein-Volhard, 1991). Numerous studies demonstrate HOM-C protein binding to multiple, clustered recognition sites. Multiple binding sites were required for a measurable response in a yeast two-hybrid screen for transcriptional activation, even when using high-affinity HOM-C protein recognition sites (Ekker *et al*., 1992). Known Ubx target sequences contain multiple 5′-TAAT-3′ repeats, and the Ubx protein can protect regions of DNA up to 87 kb (Beachy *et al*., 1988), although the minimum consensus sequence for Ubx binding is only 9 bp (Ekker *et al*., 1992). Further, Ubx binding is increasingly stabilized by cooperative interactions resulting from clustered binding (Beachy *et al*., 1993). Interacting sites are not, however, always closely clustered. They may lie as much as 200 bp apart, with their interaction involving a DNA looping mechanism. An example of cooperative binding, important to development, occurs during haltere/wing development. Ubx represses *spalt major* (*salm*), a gene involved in wing patterning, to promote haltere formation, and it does so in the absence of either Exd or Hth through a number of Ubx monomer binding sites (Galant *et al*., 2002). Taken together, these studies provide evidence for HOM-C target regulation in the absence of known cofactors. Concentration-dependent HOM-C target activation may provide an additional mechanism to guide developmental specificity, whether acting alone or in concert with currently unrecognized factors.

For the HOM-C proteins to direct the specification of segment identities, it is apparent that additional factors or mechanisms are required beyond the simple binding of a HOM-C protein to a recognition site. How might cofactors contribute to target gene selection? We mentioned above two models proposed by Biggin and McGinnis (1997) for the role of cofactors during HOM-C protein target regulation. Although there is evidence for both models, the widespread binding model appears to have the most support. But it should be pointed out that this is not likely to be a simple process involving one, two, or even three factors. More likely, the process of target gene selection involves multiple factors,

with perhaps some, like the gap gene products, being expressed prior to the HOM-C proteins. Furthermore, when thinking of cofactor function, one might expect direct interaction with the HOM-C proteins, but this need not be the case. Some proteins functioning as cofactors may not even be DNA binding proteins, but may serve as "linkers" required to stabilize interactions between the basal transcription machinery and the HOM-C proteins. Clearly, this is an area where much more investigation is needed, and because there are differences between different insect species, perhaps a comparative study can yield some of the sought-after answers.

1.8.6. Targets of the HOM-C Proteins and Functional Specificity

Adam Wilkins (1986), challenges:

> Isn't it a rather large leap from transcription-regulation, the assumed forte of homeo box-containing genes, to explaining the large-scale interaction and movements of cells that comprise morphogenesis and pattern formation? ... the rush to pin so much on the homeo box ... reveals the eagerness, even the desperation of the molecular-developmental biologists to find universal or, at least, general principles of genetic control in development.

The *HOM-C* genes are of great interest because they drive developmental specificity, both throughout an individual organism and across phyla. Those studying animal development and evolution desire to understand the mechanisms allowing this specification to take place. Graba *et al.* (1997) state:

> The goal is to identify functions that are required to translate the positional information delivered by HOX proteins into diversified morphogenetic programmes.

Although characterization of HOM-C binding and the interactions of possible cofactors certainly contribute to understanding HOM-C function, the fact that they are so conserved and yet specify pattern in such different animal body plans is perplexing. Deciphering how this is accomplished in divergent phyla is the ultimate task. An understanding of downstream targets and how they are integrated to yield different body plans is crucial to the understanding the plasticity of development.

García-Bellido has described a model by which homeotic genes might function. As "selector" genes, HOM-C products would control developmental pathways by regulating the action of "realizator" genes. The "realizator" gene products would directly define and control "morphogenic cell properties" (such as mitosis, cell recognition, cell adhesion properties, and cell death), to produce specific cell types and morphologies (García-Bellido, 1977). In such a way, these target, "realizator" genes could allow individual, regionally expressed *HOM-C* genes to direct developmentally specific characteristics through a sequence of steps similar to those of a metabolic pathway.

Despite over 20 years of intensive research into the nature and function of the *HOM-C* genes, identification of target genes has proven illusive. In a 1997 review, Graba *et al.* (1997) identify only 19 known HOM-C protein targets. Since that time, at least 13 additional HOM-C target genes have been identified, and a compilation of known HOM-C target genes appears in **Table 2**. On the basis of functional characterization, these genes fall into four categories. The first one corresponds to García-Bellido's "realizator" genes, being directly involved in modulating cellular processes. A second category contains genes whose products are involved in signal transduction. There are a few target genes whose functions are unknown, and finally, the majority of known HOM-C target genes are, themselves, transcription factors. Based on the number of developmental processes likely to be modulated by the *HOM-C* genes, and experimental results from molecular studies, Akam (1998) proposes that these "versatile generalists" might direct as many as 1000 downstream targets, each.

1.8.6.1. The Search for Target Genes

There are characteristics inherent to the *HOM-C* genes that make the identification and characterization of target genes difficult. As discussed previously, the HOM-C proteins have similar *in vitro* binding properties, recognizing a consensus core sequence of 5′-TAAT-3′. This can prove problematic when attempting *in vitro* screens for target promoter sequences, as promiscuous binding to sites lacking *in vivo* significance can occur. Several of the *HOM-C* genes have overlapping expression domains, and target gene regulation may require input from multiple *HOM-C* genes. In such a case, the removal of one HOM-C protein may not significantly effect target gene action. A single target gene also may be regulated in adjacent regions by different HOM-C proteins, as is illustrated by the activation of *tsh* activity in the anterior midgut by Antp and in the central midgut by Ubx and Abd-A (Mathies *et al.*, 1994). Cross-regulation between the *HOM-C* genes also muddies the waters of target gene identification. It can be unclear whether an observed effect results directly from the loss of one HOM-C protein, or indirectly because of the ability of the *HOM-C* genes to cross-regulate one another. The

control regions of potential target genes can be quite large, often up to 100 kb, making systematic evaluation of potential regulatory sites challenging, and also making it difficult to ascertain if an observed HOM-C protein's effect is direct or indirect. HOM-C protein action can be non cell autonomous, acting through signaling cascades and leading to effects outside of the HOM-C protein's expression domain, and in adjacent germ layers. Finally, some *HOM-C* genes have received more attention, and thus may appear more amenable to the search for target genes. Genes under the control of Antp, Ubx and/or Abd-A make up the majority of the characterized target genes, while the more anterior HOM-C proteins (LB, Pb, Dfd, Scr*)* have far fewer or no characterized targets outside of the *HOM-C* genes themselves.

Many of the identified HOM-C target genes were previously characterized genes whose expression or function gave cause to suspect HOM-C protein control. There have been, however, a number of *in vitro* and *in vivo* screening techniques that have been employed to identify other HOM-C protein targets, with varying degrees of success (for examples, see Gould *et al*., 1990; Gould and White, 1992; Graba *et al*., 1992; Mahaffey *et al*., 1993; Feinstein *et al*., 1995; Mastick *et al*., 1995; Merabet *et al*., 2002; Marchetti *et al*., 2003). Common *in vitro* screening techniques include protein–DNA interaction screens in yeast and immunoprecipitation of bound DNA fragments with HOM-C protein antibodies. *In vivo* techniques include the use of enhancer trapping and deficiency or mutagenesis screens. Other screening techniques combine elements of both, such as subtractive hybridization and chromatin immunoprecipitation. Each approach has both advantages and drawbacks. *In vivo* studies can be quite time consuming, and sometimes produce target genes that are difficult to characterize further as to their function and the directness of HOM-C protein regulation.

Yeast reporter assays can be useful in screening a large number of genomic fragments quickly and efficiently, but nonphysiological conditions, alterations in chromatin structure, and the lack of other interacting proteins can lead to imprecise results. In one such study, Mastick *et al.* (1995) sought to identify genes directly regulated by the Ubx protein. Fifteen per cent of the genome was searched, and based on fortuitous sequence alone, at least 500 interacting sites were expected. In fact, only 53 genomic fragments were recovered, and of those, only three appeared to be associated with Ubx target regulation.

Chromatin immunoprecipitation, when utilizing DNA–protein complexes cross-linked *in vivo* at physiological conditions, can be useful in identifying novel targets of direct HOM-C regulation, but requires an antibody against the HOM-C protein of interest, and results can be affected by cloning efficiencies. Also, if true, the widespread binding model would predict the recovery of a large number of DNA sites to which the HOM-C proteins bind, but many will have no endogenous regulatory effect.

Subtractive hybridization allows the sorting of transcripts that differ between normal individuals and individuals with altered HOM-C function, although hybridization conditions and cDNA synthesis can strongly influence results. Further, if target gene activation requires several HOM-C proteins, it may not be identified by such an approach.

Marchetti *et al.* took a cytological approach to identifying targets of the *BX-C* genes through immunostaining of polytene chromosomes taken from larval fat bodies (Marchetti *et al*., 2003). Although not as endoreplicated as the salivary gland polytene chromosomes, adequate BX-C protein binding was detected to allow the mapping of more than 300 binding sites. Each site bound one or more of the BX-C proteins, and several of these sites corresponded to known BX-C target genes. Differential patterns of BX-C binding were observed when polytene chromosomes from the fat bodies and salivary glands were compared, suggesting tissue-specific activity. As the *BX-C* genes are normally expressed in the fat bodies, this approach may be more likely to identify genuine binding targets, when compared to studies utilizing Ubx overexpression in the salivary glands (Botas and Auwers, 1996).

One remaining strategy that has not yet provided additional HOM-C targets is that of whole genome microarray analysis. This technique has been used to identify candidate genes involved in dorsal–ventral patterning, circadian rhythms, and immune response (Irving *et al*., 2001; McDonald and Rosbash, 2001; Stathopoulos *et al*., 2001), and may hold the same promise for further HOM-C target discovery.

1.8.6.2. Possible Modes of HOM-C Target Activation

The HOM-C proteins could regulate, directly, a vast number of individual target genes in combinations required for regional specification. Alternately, the HOM-C proteins could function primarily through the regulation of a few downstream transcription factors to activate regional, developmentally specific genetic cascades. In most cases, the line of control between the *HOM-C* genes and downstream targets is unclear. Of the target genes summarized in **Table 2**, only eight have been demonstrated to be directly regulated by a HOM-C protein. Of those

Table 2 *Drosophila* HOM-C target genes

with characterized direct interactions, most are either transcription factors or signaling molecules, and not the "realizator" genes envisioned by García-Bellido (1977). Based on the known functions of target genes currently characterized, it appears that some combination of these two modes of action is likely at work.

1.8.6.3. The Concentration of a HOM-C Protein Can Direct Target Activation

The concentration of a HOM-C protein can influence its downstream effects, as illustrated by phenotypic differences between null and hypomorphic alleles. For example, null *pb* mutants have a strong transformation of mouthparts to leg, while a hypomorphic *pb* allele results in the transformation of mouthparts to antenna or a combination of leg and antenna (Kaufman, 1978; Pultz *et al*., 1988). Using a transgenic heat shock-inducible *pb* construct, Cribbs *et al*. (1995) further demonstrated that a defined threshold concentration of Pb is required to overcome the dominant antennae to leg phenotype of an *Antp* mutant.

Ubx provides a second example of concentration dependent action. Ubx is expressed, endogenously, at different levels in parasegments 5 and 6, with the higher concentration in parasegment 6. Increased expression of Ubx in parasegment 5 can alter the identity of that region towards the identity of parasegment 6, as evidenced in the larval denticle belts and abdominal imaginal histoblast cells (Smolik-Utlaut, 1990; Frayne and Sato, 1991).

Because variation in HOM-C protein concentration can alter the morphological outcome, it is likely that activation of some specific target genes is concentration dependent, possibly acting via cooperative binding at multiple, clustered recognition sites (see Section 1.8.5.9). Varying the number of HOM-C monomer binding sites in target promoters and/or enhancers could define, in part, a concentration dependency for gene regulation. What is apparent is that the simple presence or absence of a HOM-C protein, at least in some cases, is insufficient to control differing morphological specificity.

1.8.6.4. Beyond Targets: HOM-C Protein Regulation of Developmental Processes

To understand the mechanisms by which the HOM-C proteins control body patterning, it is essential to look beyond single target genes, and attempt to discern their function in the context of a larger developmental process. Insect appendage development provides such an opportunity (see **Chapter 1.9**), as the adult insect has appendages on different segments, arising from both dorsal and ventral body regions, and specified by different *HOM-C* genes. The ability of a *HOM-C* gene product to specify the patterning of entire appendages is evidenced by the famous homeotic phenotypes that led to their discovery. Morata (2001) presents a model for appendage specification in which the regional expression of HOM-C proteins provides segment or regional specific identity (i.e., antennae vs. leg), while the signaling molecules provide the dorsal/ventral pattern cues (i.e., wing/haltere vs. leg). In Morata's model, *pb* acts to specify the proboscis, *Scr* to specify the first thoracic leg, *Antp* to specify the second thoracic leg, and *Ubx* to specify the third thoracic leg, while also repressing wing formation in favor of haltere development.

The HOM-C proteins can also act regionally, across segments, in appendage specification. For example, Antp is required to repress antennal development in all leg discs, and does so by repressing the expression of *hth*. This repression is required for the appropriate patterning of the distal and medial leg regions, as one *hth* function is that of an antennal selector gene (Casares and Mann, 2001). Ubx blocks the entire appendage development program in the anterior *Drosophila* abdomen via the direct repression of the leg selector gene *Dll* (Vachon *et al*., 1991). This requirement is demonstrated by the appearance of abdominal legs in some Ubx mutants (Lewis, 1978).

Ubx also has multiple levels of hierarchical control in specifying the third thoracic haltere. Weatherbee *et al*. (1998) investigated the control exerted by *Ubx* activity in the haltere over known wing patterning genes, while attempting to better define the developmental processes differentiating the haltere and the wing. Not surprisingly, they found that Ubx represses wing-specific genes; however, control beyond that initial level of repression was also observed. Ectopic expression of *vestigial* (*vg*) (required for wing formation and repressed by Ubx in the haltere) does not create ectopic wing tissue in the haltere, suggesting that Ubx is continuing to repress genes downstream of *vg*. Furthermore, normal haltere patterning requires Ubx function throughout larval development, indicating that Ubx does not simply function as an upstream initiator of the haltere developmental cascade.

We have discussed the probability of a large number of target genes for each HOM-C protein, and given examples in which a number of target genes are known to affect a single developmental process. Studies on the *Drosophila* larval oenocyte provide a well-characterized example of a how a single HOM-C protein can direct the fate of a single cell. The larval oenocyte is a secretory cell derived from the dorsal ectoderm, and is found in clusters of

about six cells in the first through seventh abdominal segments. Oenocyte precursor cells delaminate from the dorsolateral ectoderm at the extended germ band stage, and differentiate in response to induction by C1 precursor cells, which also give rise to chordotonal sensory organs (see **Chapter 1.11**). A simplified diagram of this pathway is depicted in Figure 13. Although the C1 precursor cells and the ectodermal oenocyte precursor cells, prepatterned by Spalt major (Salm) are present in both the thoracic and abdominal segments, epidermal growth factor receptor (EGFR) activity is present only around the abdominal C1 cells, limiting oenocyte formation to these segments. The *spitz* (*spi*) gene product, encoding an EGFR ligand, is secreted by the abdominal C1 cells, and received by the oenocyte precursor cells, leading to the oenocyte specific gate (Elstob *et al.*, 2001; Rusten *et al.*, 2001). The *rhomboid* (*rho*) gene encodes a processing factor for the Spi ligand, modifying a membrane bound form of Spi (mSpi) to a secreted form (sSpi). Although *rho* is initially activated by *atonal* (*ato*) in the C1 cells, a burst of *abd-A* and *exd* expression in the abdominal segments is required to maintain *rho* transcription and allow the processing of membrane bound Spi in the Golgi apparatus (by Rho)

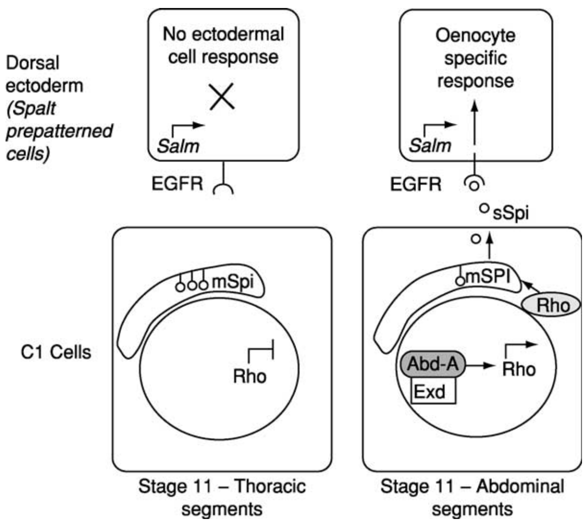

Figure 13 *Drosophila* Abd-A regulates a single principal target, *rho*, to direct larval oenocyte differentiation. The *spalt major* gene (*salm*) is transcribed in the dorsal embryonic ectoderm throughout the thoracic and abdominal segments. Rho is a processing factor, which acts in the Golgi apparatus to modify the membrane-bound form of the Spitz ligand (mSpi) to the secreted form (sSpi). In the abdominal segments at the germ band extended stage (Stage 11), a burst of *abd-A* and *exd* expression is required for *rho* transcription, allowing the production of sSpi and resulting in oenocyte-specific epidermal growth factor receptor (EGFR) output. Because Abd-A is not expressed in the thoracic cells and *rho* activity is absent, sSpi is not present to activate the oenocyte differentiation pathway.

to the secreted form (Brodu *et al.*, 2002). The processed Spi is then secreted, can activate EGFR and induce the *salm*-prepatterned ectodermal cells to form oenocytes. As oenocytes are found in a wide variety of both long and short germ insects, this system may provide a nice model for comparative insect studies of HOM-C target regulation.

Comparative studies of developmental processes in other insects are critical to the further understanding *HOM-C* gene function. The ability of the *HOM-C* genes to direct developmental processes is well documented in other insects (for examples, see Beeman *et al.*, 1989, 1993; Nagata *et al.*, 1996). Identifying the *Drosophila HOM-C* gene homologs, and their downstream targets directing these developmental processes, is beginning to provide interesting data regarding homeotic gene control of development. The direction of gnathal appendage development by the *HOM-C* genes provides an example.

In *Drosophila*, the *HOM-C* genes *Scr* and *pb* are required for appropriate patterning of the proboscis, and this specification requires suppression or down-regulation of antennal and leg-specific genes in the labial disc, such as *exd, dachshund (dac)*, *salm*, and *Dll*. For example, *pb* limits the expression of *Dll* to a compact crescent-shaped domain within the developing labial appendage (Abzhanov *et al.*, 2001). The loss of *pb* causes an increase and an expansion of *Dll* expression, leading to the leg or partial antennal transformations observed in *pb* mutants. The loss of both *pb* and *Scr* causes a transformation of the proboscis to the "ground state" of antenna. Studies undertaken in *Tribolium* indicate that these genes function similarly to direct proboscis development as well. The loss of *mxp* (*pb* homolog) in the labial appendage bud causes a transformation of the labial palp to leg, and double mutants for *Cx* (*Scr* homolog) and *mxp*, develop antenna in place of the palps, similar to the fly. Unlike *Drosophila*, however, *Dll* expression in the *Tribolium* labial appendage is not significantly altered in *mxp* mutants (DeCamillis *et al.*, 2001). It will be interesting to see the effects of *mxp* and *Cx* loss on other leg/antennal patterning genes.

Appropriate *Dll* expression is required for the distal development of all *Drosophila* appendages, and *Dll* is also expressed in the developing appendages of other insects. Its pattern of expression is well conserved, as observed in *Tribolium*, *Thermobia*, *Acheta*, *Oncopeltus*, *Precis*, and *Neodiprion*, but there do appear to be some differences in both expression and regulation (Weatherbee *et al.*, 1999; Beermann *et al.*, 2001; Suzuki and Palopoli, 2001; Rogers *et al.*, 2002). Like in *Drosophila*, *Tribolium* requires the repression of *Dll* to suppress the

appendage development pathway, but rather than utilizing Utx (Ubx homolog) and A (Abd-A homolog) for this function, A alone prevents *Dll* expression in the *Tribolium* larval abdomen (Lewis *et al.*, 2000). Utx, instead, appears to modulate patterning of a first abdominal appendage, the pleuropodia. Lepidopteran larvae, which have abdominal prolegs not found in *Drosophila* or *Tribolium* larvae, express *Dll* in the abdominal regions, in which these legs will form. Correspondingly, there are "holes" in the *BX-C* gene expression domains in the abdomen, allowing *Dll* expression and indicating that the lepidopteran *BX-C* genes may have a limb-repressing role. Studies in *Neodiprion* larvae reveal the conservation of BX-C control of *Dll* expression, even though the developmental process is altered (Suzuki and Palopoli, 2001). In contrast to lepidopteran larvae, *Neodiprion* larvae lack abdominal *Dll* expression even though these larvae develop abdominal prolegs. Concomitantly, the expression of the *BX-C* genes is found throughout the abdomen, including the developing prolegs. This reflects a conservation of the BX-C/*Dll* regulatory relationship, but a possibly convergent *Neodiprion* developmental pathway for abdominal prolegs, when compared to Lepidoptera. *Dll* is also a target of Ubx in the lepidopteran hindwing, which derives from the third thoracic segment. In contrast to the highly modified haltere of *Drosophila*, butterflies have well developed hindwings. As might be expected, several of the wing-specific genes that are repressed by Ubx in the *Drosophila* haltere remain under Ubx control in the butterfly, but are differentially regulated to allow hindwing development and patterning (Weatherbee *et al.*, 1999). These examples illustrate how differences in HOM-C gene target regulation may correlate to different developmental outcomes between insect species.

The HOM-C proteins can, in some developmental processes, directly regulate a large number of target genes to dictate regional specification. In other processes, however, far fewer targets may be required, with the primary targets being other transcription factors or signaling molecules. Specification of body regions, such as the wing or midgut, appears to be complex and involve a large number of downstream factors. In contrast, specifying the identity of only a few cells, as illustrated by the oenocyte case, can require only a single HOM-C responding gene.

1.8.7. Looking Forward

Our further understanding of how *HOM-C* gene function directs axial patterning requires a thorough understanding of the biological processes guided by the *HOM-C* genes, the target genes responding to HOM-C protein regulation, and comparative studies involving nondrosophilid insects. A three-step approach begins with the identification of additional *HOM-C* guided developmental processes. These may be as large and complex as neural development (see **Chapters 1.10** and **2.3**), or may be as specific as the patterning of a single sensory cell (see **Chapters 1.12** and **1.11**), or even the regulation of a single gene. For example, recent studies into the process of larval salivary gland development (see **Chapter 2.10**), are providing insights into how Scr function establishes cell fate and tissue morphology (Abrams *et al.*, 2003; Haberman *et al.*, 2003). Next, characterizing the manner in which the HOM-C proteins then direct specific processes through downstream targets may shed light on the various mechanisms by which they govern pattern formation. Dfd, for example, was recently shown to directly regulate expression of the proapoptotic gene, *reaper*, in sculpting the *Drosophila* embryonic gnathal lobes through the initiation of programmed cell death (Lohmann *et al.*, 2002; see also **Chapter 2.5**).

Finally, comparisons of developmental processes and genetic cascades between insect species and noninsect arthropods are critical for addressing long-standing questions regarding the role of *HOM-C/HOX* genes in both development and evolution. The success of RNAi is now allowing the characterization of gene function in a growing number of nonmodel insects (Brown *et al.*, 1999; Denell and Shippy, 2001) such as *Thermobia* and *Oncopeltus*, without the generation of mutant strains. Recent studies by Galant and Carroll (2002) and Ronshaugen *et al.* (2002) correlate functional changes in Ubx, between insect and other arthropods, to the transition, in arthropods, from legs on every segment to legs limited to only the thoracic segments. Studies such as these will certainly continue and grow to include a wide variety of insects and other arthropods. When expanded to include downstream target genes, this work should provide valuable insights correlating changes in *HOM-C* directed genetic cascades to differing morphologies or developmental outcomes.

Acknowledgments

Although the authors have attempted to be as comprehensive as possible, due to space constraints, they regret they were unable to cite all relevant literature on this topic and offer sincere apologies to those authors whose work they are unable to include.

1.9 *Drosophila* Limb Development

U Weihe, M Milán, and S M Cohen, European Molecular Biology Laboratory, Heidelberg, Germany

1.9.1. *Drosophila* Limb Development as a Model System

A central question in developmental biology is how growth and patterning of tissues are controlled at a molecular and genetic level. *Drosophila melanogaster* has become an important model system to approach this problem because of its suitability for genetic and molecular manipulations and its well-described developmental biology. Systematic genetic screens for loss-of-function mutations (Nüsslein-Volhard and Wieschaus, 1980), gain-of-function phenotypes (Rorth, 1996; Rorth *et al.*, 1998), and the detection of gene expression patterns by enhancer trapping (Bellen *et al.*, 1989; Calleja *et al.*, 1996) have revealed many of the genes involved in developmentally important processes (for a recent review, see **Chapter 1.8**). In addition, the completion of the genomic sequencing project for *Drosophila melanogaster* (Adams *et al.*, 2000) and, recently, for *D. pseudoobscura,* makes it possible to employ reverse genetic approaches such as RNA-mediated interference (Kennerdell and Carthew, 1998) and targeted gene disruption (Rong and Golic, 2000; Rong *et al.*, 2002) as well as genome-wide expression analyses (Furlong *et al.*, 2001; Jasper *et al.*, 2001; Arbeitman *et al.*, 2002; Klebes *et al.*, 2002; Butler *et al.*, 2003) to address a wide variety of questions concerning the developmental biology of the fruitfly and related insects.

The appendages of *Drosophila* have proven to be ideal models for the investigation of limb development. Like the appendages of vertebrates, they develop as outgrowths of the body wall (although these outgrowths are initially topologically inside the fly embryo/larva). Early in embryonic development, imaginal cells (i.e., cells that contribute to the adult animal, the "imago") segregate from their neighbors by invagination from the ectoderm (Bate and Martinez-Arias, 1991). Later, these clusters of cells separate into ventral and dorsal appendage precursors (Wieschaus and Gehring, 1976; Cohen *et al.*, 1991, 1993; Averof and Cohen, 1997) and form saclike structures called imaginal discs (**Figure 1**). Although each disc is a continuous epithelial monolayer, opposite sides of the sac acquire different properties. Most structures of the adult limb and of the neighboring body wall are derived from one side of the sac, which forms a highly folded pseudostratified epithelium (review: Cohen, 1993). It is in this epithelium that the major patterning events take place. The other side of the sac forms a squamous epithelium called the peripodial membrane, which has recently been reported to contribute to some aspects of patterning and growth

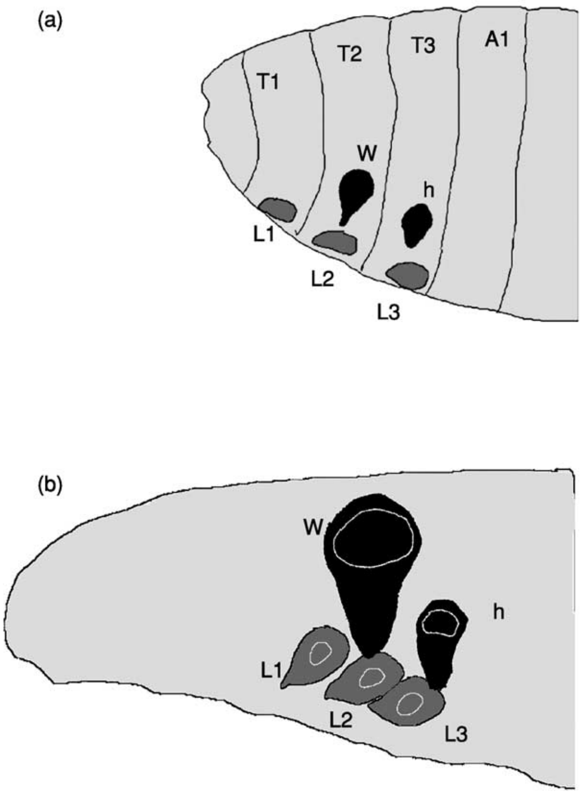

Figure 1 Specification of imaginal discs. (a) Drawing of the anterior half of a stage 17 *Drosophila* embryo (lateral view). Primordia of the imaginal discs are shown in dark gray (ventral appendages) or black (dorsal appendages). T1–3, thoracic segments 1-3; A1, abdominal segment 1; w, wing disc; h, haltere disc; L1–3 – first, second, and third leg discs. (b) Drawing of a third instar larva, showing the different imaginal discs.

control in the pseudostratified epithelial layer (Cho *et al*., 2000; Gibson and Schubiger, 2000, 2001; Ramirez-Weber and Kornberg, 2000).

Imaginal discs grow considerably during larval stages by exponential cell proliferation (García-Bellido and Merriam, 1971a; Madhavan and Schneiderman, 1977). The wing imaginal disc consists of ~50 cells at the end of embryogenesis and grows to ~50 000 cells at pupariation. Patterning and organ size regulation are, in principle, disc-autonomous processes even though disc growth requires the input of growth factors and hormones from nonimaginal tissues (review: Bryant and Simpson, 1984). *Drosophila* as a higher dipteran insect undergoes complete metamorphosis. During this process the primordium extends along its proximal–distal axis by turning inside out through the lumen (so that the appendages come to lie topologically outside the body wall after disc eversion). Actual differentiation of many adult structures (such as wing margin sensory organs, etc.) does not begin until metamorphosis. However, the structures of the adult organ reflect patterning and growth processes that occur during development.

1.9.2. Developmental Subdivisions of the Limb Primordia

The establishment of the three major axes of the limbs takes place during imaginal disc development. The primordia receive the patterning cues needed to generate an anterior–posterior, dorsal–ventral, and proximal–distal axes (**Figure 2**). Diffusible signals termed morphogens (Turing, 1952) provide cells within the epithelium with positional information (Wolpert, 1969). Axis formation involves a variety of different responses to this positional information. Changes in gene expression control cell identity, with concomitant effects on growth and differentiation.

The establishment of the limb axes depends on subdivision of their primordia into distinct functional units. The first subdivision occurs in embryogenesis in the epithelial cell layer from which the discs derive and so is inherited by the nascent disc primordia (Cohen *et al*., 1993). Subsequent subdivisions arise *de novo* in the imaginal discs during larval stages. Segregation of these cell populations seems to involve differences in cell affinity (reviews: Dahmann and Basler, 1999; McNeill, 2000; Irvine and Rauskolb, 2001). Two mechanistically distinct modes of subdivision have been described:

1. *Heritable subdivisions*. These subdivisions are based on the establishment of a heritable pattern of transcription factor expression that confers a specific identity on a field of cells. The first such subdivision was detected in the *Drosophila* wing between anterior (A) and posterior (P) "compartments" (García-Bellido *et al*., 1973, 1976). An analogous AP subdivision exists in the leg imaginal disc (Steiner, 1976). The wing disc is further subdivided into dorsal (D) and ventral (V) compartments (Diaz-Benjumea and Cohen, 1993; Blair *et al*., 1994; García-Bellido *et al*., 1976) (**Figure 2c** and **d**).
2. *Nonheritable subdivisions*. As an alternative to the stable, heritable mechanism, cell populations can also be subdivided by cell interactions. Continuous input of positional information can instruct cells about their position within a tissue and specify responses that separate cell populations. These cues can be transmitted either through local interactions with neighboring cells or through the reception of long-range morphogen gradient cues (reviews: Strigini and Cohen, 1999; Gurdon and Bourillot, 2001; Freeman and Gurdon, 2002). Cells are able to move

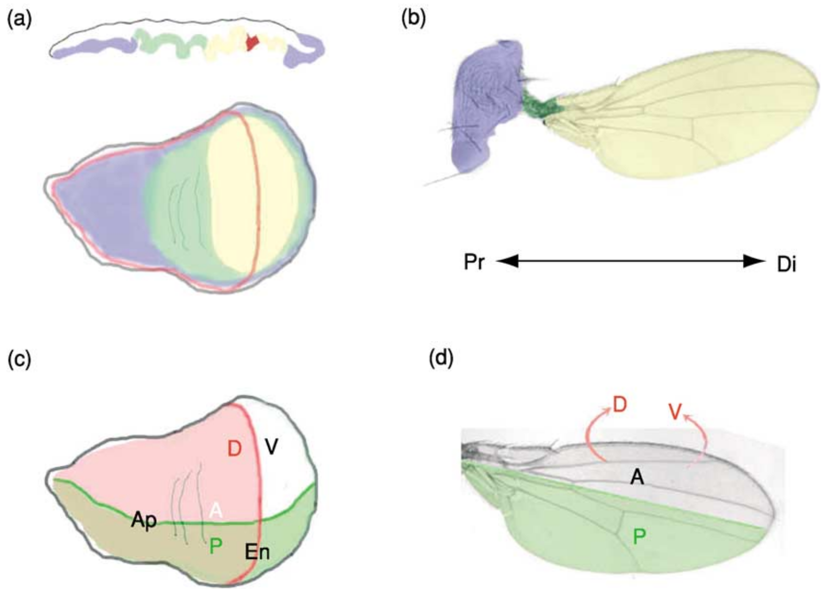

Figure 2 Organization of the axes in the wing imaginal disc. (a) Drawing of a wing imaginal disc, lateral view (upper panel) and apical view (lower panel). In the lateral view the peripodial membrane is depicted as a thin line, over the pseudostratified epithelium, proximal (Pr) structures pointing to the left and distal (Di) ones to the right. The colors represent the different adult structures that develop from the wing imaginal disc. Blue, notum; green, hinge region; yellow, wing pouch; the red line represents the dorsal–ventral boundary. (b) Picture of an adult wing. Color code as in (a). (c) Organization of the anterior–posterior (AP) and dorsal–ventral (DV) boundary within the imaginal disc. The red line represents the DV lineage restriction boundary. Apterous (Ap) is expressed in the D compartment (pink). The green line represents the AP compartment boundary; Engrailed (En) expression in the P compartment is shown in green. (d) Adult wing showing the wing's AP and DV axes.

between subdivisions, changing their expression profiles according to the position-dependent cues they receive (Campbell and Tomlinson, 1998; Weigmann and Cohen, 1999; Jungbluth *et al.*, 2001) (**Figure 2a** and **b**).

1.9.2.1. Heritable Subdivisions: Compartments

The first clues to understanding compartmentalization came from using mitotic recombination to genetically mark cells and their descendants in the *Drosophila* wing. Patches of cells homozygous for a recessive, cell-autonomous marker (e.g., cuticle pigmentation, shape of wing hairs) in an otherwise heterozygous background occupy random positions and usually have irregular borders. Clones of cells abutting the border between A and P compartments (slightly anterior to vein four in the adult wing) (**Figure 2d**) show smooth borders and remain within their compartment of origin, suggesting that cells cannot cross this "compartment boundary," even if they are given a relative growth advantage (Morata and Ripoll, 1975) (**Figure 3**). Molecular markers (e.g., green fluorescent protein (GFP) and lacZ) (Xu and Rubin, 1993) have made it possible to investigate in great detail how the compartment boundary is established and maintained (Blair and Ralston, 1997; Rodriguez and Basler, 1997; reviews: Blair, 1995; Brook *et al.*, 1996).

According to the definition of compartments, these comprise three features:

1. Compartments are subdomains of a tissue that are separated by a boundary of cell lineage restriction.
2. Compartment boundaries show organizing activity that patterns the surrounding tissue.
3. Compartments divide tissues in terms of cell fate/identity.

1.9.2.1.1. Selector genes The establishment of compartments as units of lineage restriction led to the idea that the activity of certain genes "selects" these units for a specific fate (García-Bellido, 1975). The original definition of a "selector gene" includes the following properties:

1. The functional domain is limited by a lineage restriction boundary (compartment boundary). Selector genes confer cell affinity differences that prevent mixing of cells from different compartments.
2. Selector genes have an instructive developmental role.

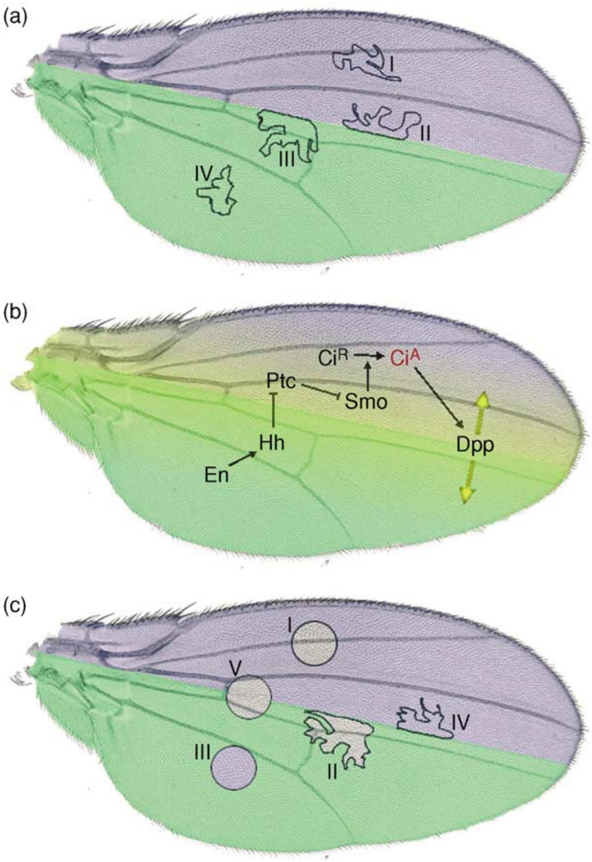

Figure 3 AP compartment formation in the *Drosophila* wing. Anterior cells are shaded blue, posterior cells are shaded green. (a) Clones of wild-type cells have irregular borders and occupy random positions within a compartment (I and IV) but never cross the AP compartment boundary. They show smooth edges when they happen to contact it (II and III). (b) Simplified schematic view of Hedgehog (Hh)-mediated signaling across the AP boundary. Hh signaling ultimately results in conversion of Cubitus interrupts (Ci) from its repressor form (Ci^R) to a transcriptional activator Ci^A. Ci^A activates the long-range morphogen Decapentaplegic (Dpp) (yellow) which spreads from the AP boundary to further pattern the wing. (c) Scheme to show the influence of Engrailed (En) and Hh pathway mutations on clone shape and localization. Posterior clones that lack En (or ectopically express Ci) either sort into the anterior compartment (IV) or round up (III). Anterior clones lacking Smoothened (Smo) (or Ci) form round clones within the anterior compartment (I) or sort into the posterior (II). Clones of cells mutant for both En and Ci have different adhesive properties from both A and P cells and can form round clones at the AP boundary (V). For other protein definitions, see text and appendix. (Modified from Irvine, K.D., Rauskolb, C. **2001**. Boundaries in development: formation and function. *Annu. Rev. Cell Devel. Biol. 17*, 189–214.)

3. Several selector genes can act in a combinatorial mode.
4. Selector genes act strictly autonomously to specify compartment-specific properties (e.g., cell fate).

The term "selector gene" is often misused to describe genes that confer regional identity in a manner not linked to lineage-restricted compartments (reviews: Mann and Morata, 2000; Mann and Carroll, 2002). In this review, the use of the term selector gene is limited to only those factors that fulfill all the criteria mentioned above. Other genes that specify subdivisions but do not fulfill these criteria will be referred to as "selector-like" or "regional identity" genes. This distinction is considered to be important because of the underlying mechanistic differences between the two modes of regionalization. Compartment boundaries defined by selector genes serve as the sources of organizing signals, which is not usually the case for noncompartmental subdivisions.

1.9.2.1.1.1. Engrailed/Invected: posterior compartment selector genes During segmentation in the embryo, P cells are programmed to express the homeodomain transcription factors Engrailed (En) and Invected (Inv) (Kornberg *et al.*, 1985) (for a list of all genes and proteins discussed in this chapter, see appendix). Even though the signals that lead to the induction of En and Inv are transient, their expression becomes heritably transmitted and is inherited by the nascent imaginal disc primordia when they form in the embryo (Cohen *et al.*, 1993). This is likely to depend on the epigenetic mechanisms based on chromatin remodeling by Polycomb (Pc) and Trithorax (Trx) group proteins (Ingham, 1981; Busturia and Morata, 1988; see **Chapter 1.8**). The En/Inv complex controls all aspects of posterior fate in the wing and leg (**Figure 2c and d**). Cells mutant for *en* show some anterior character (García-Bellido and Santamaria, 1972; Morata and Lawrence, 1975; Lawrence and Struhl, 1982). However, P cells mutant for both *en/inv* are indistinguishable from A cells (Kornberg, 1981; Tabata *et al.*, 1995; Zecca *et al.*, 1995; Blair and Ralston, 1997; Lawrence *et al.*, 1999a) (**Figure 3**). Inv alone mainly confers P identity in terms of differentiation (Simmonds *et al.*, 1995). En was shown to work as a transcriptional repressor (Jaynes and O'Farrell, 1988, 1991; Han *et al.*, 1989; Ohkuma *et al.*, 1990). The En repressor domain very strongly represses promoters activated by a variety of different activator proteins (Han and Manley, 1993; Smith and Jaynes, 1996). En/Inv are highly conserved and fulfill similar roles in other invertebrate species (Patel *et al.*, 1989).

1.9.2.1.1.2. Apterous: dorsal compartment selector gene During larval development, the wing imaginal disc is further subdivided by a DV compartment boundary (García-Bellido *et al.*, 1976). The gene responsible for the specification of all aspects of

dorsal cell developement is the transcription factor Apterous (Ap) (Blair, 1993; Diaz-Benjumea and Cohen, 1993). The gene *apterous* (*ap*) conforms to the classic definition of a selector gene. Ap activity generates an affinity difference between dorsal and ventral cells and thereby produces the DV lineage boundary. Ap selects between alternative cell fates (D and V) in an autonomous manner and acts in a combinatorial mode with the posterior selector genes *en* and *inve* (**Figure 2c** and **d**).

Early in larval development, the wing imaginal disc is patterned by two opposing signaling pathways, the Wingless (Wg) and epidermal growth factor (EGF) pathways. Hedgehog (Hh) induces Wg in the V–A domain, where it is required to specify the primordium of the wing blade (as opposed to the body wall) (Williams *et al*., 1993; Ng *et al*., 1996; Klein and Martinez-Arias, 1998) (**Figure 4a**). The *vein* (*vn*)-dependent epidermal growth factor receptor (EGFR) signaling has a dual role in early wing disc development (Wang *et al*., 2000; Zecca and Struhl, 2002a, 2002b). First, it instructs cells to adopt body wall fate by antagonizing wing fate and activating notum-specifying genes. The mutually antagonistic repression of the Wg and EGFR signaling pathways therefore separates the wing from the body wall field. Second, EGRF signaling directs cells to become part of the dorsal compartment by inducing the dorsal selector gene *ap* (**Figure 4a**). Thus, the antagonism of EGFR and Wg signaling also controls wing blade development through the initiation of DV boundary formation (**Figure 4b** and **c**).

1.9.2.1.1.1.1. Specification of dorsal cell fate through Ap Ap specifies dorsal cell fate. Removal of Ap activity causes complete transformation from D to V identity (Diaz-Benjumea and Cohen, 1993; Blair *et al*., 1994). D cells differ from V cells in the adult with respect to a set of morphological markers

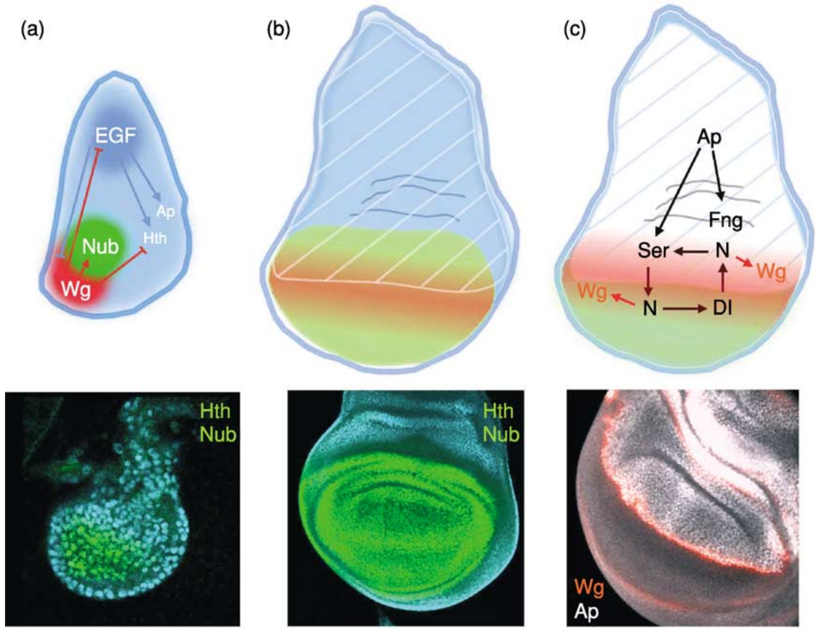

Figure 4 Establishment of the proximal–distal and dorsal–ventral boundaries. (a) (upper panel) The Wingless (Wg) and the epidermal growth factor receptor (EGFR) signaling pathways antagonize each other. Wg specifies the wing pouch through the activation of Nubbin (Nub) and Vestigial (Vg, not shown) and the repression of Vein (Vn, the ligand for the EGFR; not shown), Homothorax (Hth), Apterous (Ap), Teashirt (Tsh, not shown). Vn induces the formation of notum structures and is necessary for the activation of Ap, Hth, and Tsh, and represses the expression of Vg. Both activities together are responsible for establishment of the dorsal–ventral and proximal–distal axes. (lower panel) Single confocal section of a late second instar wing imaginal disc labeled with antibodies against Nub (green), and Hth (cyan). Nub marks the future wing pouch, while Hth marks hinge and body wall tissue. (b) (upper panel) Drawing of late third instar wing disc. The wing pouch is marked in green (Nub), notum tissue is depicted in cyan (Hth). Ap (crosshatched in white) is exclusively expressed in dorsal cells and establishes the dorsal–ventral boundary. Wg (red) is expressed at the dorsal–ventral boundary and spreads along the dorsal–ventral axis into the wing pouch. (lower panel) Late third instar wing disc labeled with anti-Nub (green) and anti-Hth (cyan) antibodies, showing the noncompartmental subdivision in notum and wing tissue. (c) (upper panel) Ap (white) induces the dorsal–ventral compartment boundary through the activation of Fringe (Fng) and Serrate (Ser) in the dorsal compartment and the repression of Delta (Dl). This leads to the activation of Notch (N) signaling at the dorsal–ventral boundary and eventually to the expression of Wg (red). (lower panel) Late third instar wing disc labeled with anti-Ap (white) and anti-Wg (red) antibodies, showing dorsal–ventral compartmentalization and dorsal–ventral organizer.

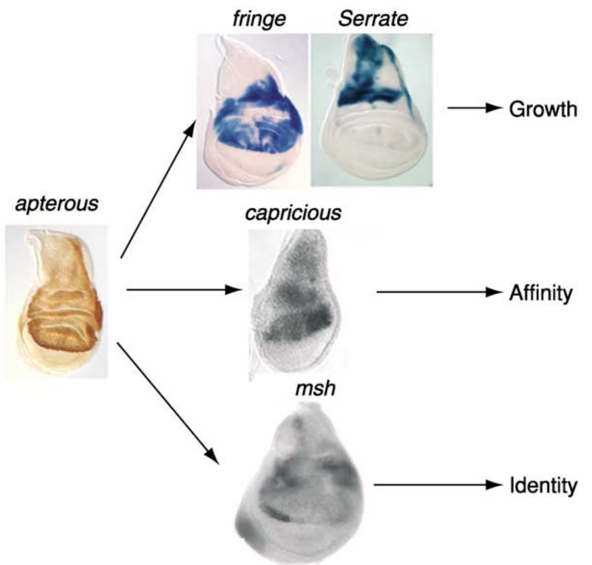

Figure 5 Summary of Apterous functions during wing development. Dorsal–ventral subdivision of the wing imaginal disc depends on the activity of Apterous (Ap) in the dorsal compartment, where it is expressed (*in situ* hybridization with a probe against *apterous*). Ap is responsible for (1) the induction of the dorsal–ventral organizer along the dorsal–ventral compartment boundary through Fringe and Serrate (X-Gal staining of enhancer trap lines inserted at the respective loci); (2) the establishment of a lineage restriction boundary between dorsal and ventral cells through induction of the affinity molecules Capricious (X-Gal staining of an enhancer trap line inserted at the *caps* locus) and Tartan (not shown) in early wing discs; and (3) dorsal specification of dorsal cell fate through Msh (*in situ* hybridization with a probe against *msh*).

such as sensory organs (see **Chapter 1.11**) and wing vein structure. It has been claimed that D cell differentiation can take place in the absence of Ap activity (Klein *et al.*, 1998). However, more careful analysis showed that the *ap* mutants used in that study were only partial loss-of-function mutations, and had enough residual Ap activity to confer dorsal cell fate (Milan and Cohen, 1999a, 2003; O'Keefe and Thomas, 2001). The *ap* confers dorsal identity by controlling expression of the homeobox gene *muscle segment homeobox (msh)* (Milan *et al.*, 2001b) (**Figure 5**). *msh* is expressed in dorsal cells in the embryonic neuroectoderm and muscle precursors (D'Alessio and Frasch, 1996; Isshiki *et al.*, 1997; Lu *et al.*, 2000). In the wing disc, *msh* is expressed in D cells where it is both necessary and sufficient to direct differentiation of dorsal cell characteristics (Milan *et al.*, 2001b). A summary of all known Apterous functions is shown in **Figure 5**.

1.9.2.1.1.1.2. Regulation of Ap activity Ap is expressed in the wing and haltere imaginal discs exclusively in D cells (Cohen *et al.*, 1992). Tight spatial and temporal regulation turned out to be essential for proper Ap activity. Ap belongs to the family of lin-11, islet-1, mec-3 (LIM)-homeodomain factors, which shares two tandemly repeated LIM domains and a homeodomain (review: Hobert and Westphal, 2000). LIM-domains are cysteine-rich zinc-finger domains that mediate protein–protein interactions (Jurata *et al.*, 1998). For LIM-homeodomain transcription factors to function, they require a class of proteins known as LIM-domain binding (LDB) or nuclear LIM interactor (NLI) (Agulnick *et al.*, 1996; Jurata *et al.*, 1996; Morcillo *et al.*, 1997; Fernandez-Funez *et al.*, 1998; review: Bach, 2000). In *Drosophila* wing development, Ap activity depends strictly on dLDB/Chip (Fernandez-Funez *et al.*, 1998). A dimer of dLDB/Chip has been shown to bridge two Ap molecules to form a tetrameric complex active *in vivo* (Milan and Cohen, 1999b; van Meyel *et al.*, 1999; Rincon-Limas *et al.*, 2000). The levels of Ap activity are further controlled both spatially and temporally during development (Milan and Cohen, 2000b). Ap regulates its own activity by inducing the expression of its target gene *Beadex/dLMO* (Milan *et al.*, 1998; Shoresch *et al.*, 1998; Zeng *et al.*, 1998). *dLMO* encodes a member of the LIM-domain only (LMO) family and contains two LIM domains highly similar to those of Ap. dLMO is able to downregulate Ap activity by binding to the LIM-interaction domains of dLDB/Chip, competing with Ap itself. Through this mechanism, Ap is inactivated (Milan *et al.*, 1998; Milan and Cohen, 1999b; van Meyel *et al.*, 1999). This limits the time window during which Ap is highly active in the dorsal compartment and during which DV boundary formation can take place. The limitation of Ap activity is essential because some of the genes regulated by Ap are used in a different developmental context later. Late in development, Serrate (Ser) and Delta (Dl) are expressed along the future veins and at both sides of the DV compartment boundary, where they contribute to the establishment of a feedback loop essential for the restriction of Notch (N) activity along veins and the DV boundary (**Figure 4c**). Continuously, high activity of Ap is not compatible with these later functions (Milan *et al.*, 1998; Milan and Cohen, 2000b; Weihe *et al.*, 2001).

The model that dLMO acts as a competitive inhibitor of Ap suggests that dLMO should displace Ap from Chip. In fact, Ap protein is destabilized in cells expressing dLMO. Interestingly, Ap appears to be destabilized in situations where it is unable to bind to DNA in active tetrameric complexes with Chip (Weihe *et al.*, 2001). dLMO competes effectively with Ap for binding to Chip, whereas

Ap competes poorly with dLMO apparently due to an intrinsic difference in the affinities of the LIM domains of Ap and dLMO. This means that dLMO is a potent inhibitor of Ap activity because it binds Chip more effectively than Ap (Weihe *et al.*, 2001).

dLDB/Chip is also involved in the activation of the *achaete–scute* (*ac-sc*) proneural complex in association with the GATA factor Pannier (Pnr). This process is important for sensory bristle patterning in the thorax (see **Chapter 1.11**). Pnr antagonizes Ap function, presumably by competitively binding to Chip. The correct stoichiometry of these three proteins is crucial for both proneural prepatterning and subdivision of the thorax (Ramain *et al.*, 2000).

1.9.2.1.2. Mechanisms of boundary formation

1.9.2.1.2.1. Affinity-based cell separation Because of the signaling interactions that ensue when A and P or D and V cells are confronted (see Section 1.9.2.1.3.2), a well-defined straight boundary between compartments is essential. Crossing of cells into the other compartments would lead to the establishment of an ectopic organizer within the wing pouch, resulting in severe morphological defects. How are cells from different compartments kept separate? Differences in cell adhesion certainly can contribute to this process. Sorting out of cell populations can be guided by both the amount and types of adhesion proteins that cells express (Steinberg and Takeichi, 1994).

One well-studied example of differential adhesion mediating morphogenesis is the sorting of the oocyte to the posterior of the ovary in *Drosophila* (see **Chapter 1.2**). The oocyte and the posterior follicle cells express higher levels of *Drosophila* EGF-domain containing cadherin (DE-cadherins), which are adhesion molecules, and catenins, which anchor the cadherins to the cytoskeleton and are necessary for strong adhesion. Loss of either cadherins or catenins leads to mislocalization of the oocyte within the ovary (Godt and Tepass, 1998; Gonzalez-Reyes and St. Johnston, 1998; review: **Chapter 1.2**). However, cadherins have not been shown to be responsible for boundary formation in the discs. Clones of cells overexpressing cadherins do sort out from surrounding cells in the discs (Dahmann and Basler, 2000), showing that the expression of adhesion molecules can, in principle, separate cell populations in imaginal discs. Affinity molecules involved in cell separation at the AP axis have not been identified yet.

Theoretically, the prospective wing margin cells (zone of nonproliferating cells (ZNCs)) could act as a physical barrier to prevent mixing of D and V compartment cells (O'Brochta and Bryant, 1985). This model predicts that the DV boundary is in fact two boundaries, one on the dorsal and one on the ventral side of the ZNC. It also requires that cells from outside the ZNC are prevented from entering it. Neither requirement was fulfilled however, when clone distribution was analyzed in discs, so the barrier model cannot explain DV boundary formation (Blair, 1993). Thus, Dorsal cells mutant for *ap* fail to respect the DV boundary and tend to sort out into the V compartment (analogous to posterior cells mutant for *en*) (**Figure 3c**). Therefore, it was hypothesized that Ap could directly regulate the expression of molecules that modify cell adhesion or affinity (Lawrence and Struhl, 1996). Indeed, *ap* controls the expression of two integrin-type adhesion molecules, PS1 and PS2. PS1 expression is activated in the D compartment by Ap activity and PS2 is restricted to V cells by repression through Ap (Blair *et al.*, 1994). However, PS1 and PS2 proved not to be involved in DV compartment formation but rather to regulate the attachment of the D and V wing blades during pupal stages (Brower and Jaffe, 1989; Blair *et al.*, 1994).

Evidence that other Ap-dependent cell interactions contribute to boundary formation has been presented (Milan *et al.*, 2001a). The *capricious (caps)* and *tartan* (*trn*) genes are targets of Ap (**Figure 5**). The genes *caps* and *trn* encode transmembrane proteins with extracellular leucine-rich repeats (LRRs) and are expressed in the D compartment during boundary formation. Caps and Tartan confer affinity for D cells, as assessed by sorting out behavior, and contribute to boundary formation, as assessed by sensitized genetic assays. However, removing both genes does not eliminate the DV boundary, indicating that other *ap* target genes may also confer D cell-affinity properties.

Taken together, the results suggest that *ap* is responsible for the specification of all aspects of D cell development in the *Drosophila* wing and works as a classical selector gene (**Figure 5**).

1.9.2.1.2.2. Signaling-based cell separation There are several examples of cell sorting processes that are clearly influenced by cellular signaling, where the mechanism may not be dependent on differences in cellular affinities per se. Rhombomeres in the vertebrate hindbrain are separated by a cell lineage restriction. Ephrin tyrosine kinase receptors and their membrane-bound Ephrin ligands are expressed in complementary rhombomeres. Both receptors and ligand are able to transduce signals. Bidirectional signaling occurs at the interface of their expression domains, causing the restriction of cell intermingling

between hindbrain segments. Unidirectional signaling is not sufficient to establish the cell lineage restriction, indicating that the ligand–receptor interaction is not sufficient to confer a cell–cell affinity difference strong enough to separate cells from different segments (Mellitzer *et al*., 1999; Xu *et al*., 1999). Many adhesion proteins form regulated connections with the cytoskeleton and participate in contact-mediated signaling (reviews: Hynes, 1999; Vleminckx and Kemler, 1999). Signaling-based repulsion or deadhesion in this case could promote segregation of cell populations. If signaling promotes reorganization of the cytoskeleton, cell interactions might be destabilized (Brückner and Klein, 1998). Repeated cycles of deadhesion and readhesion could lead to sorting out behavior.

This example is not meant to argue that cell affinity factors do not play a role in these cell sorting processes. However, they do suggest that alternative mechanisms based on signaling are possible. In fact, asymmetric signaling from P to A cells seems to affect AP boundary formation in the *Drosophila* wing. Anterior clones of cells lacking the transmembrane protein Smoothened (Smo), which is essential for *hh* signal transduction, can associate with posterior cells even though they lack En and were of anterior origin (**Figure 3c**). However, these clones do not mix perfectly with P cells either, suggesting that a contribution of *hh* signaling and En-mediated cell affinity differences, both are crucial for proper sorting of cells into the correct compartment (Blair and Ralston, 1997; Rodriguez and Basler, 1997; Lawrence *et al*., 1999b; Dahmann and Basler, 2000).

Signaling between dorsal and ventral cells contributes to D–V boundary formation. For example, Fringe-expressing clones (which have "dorsal" Notch signaling properties) are able to cross the boundary from V to D if they happen to contact it (Micchelli and Blair, 1999; Rauskolb and Irvine, 1999). However, it has been shown that Notch activation along the DV boundary in the absence of Ap is insufficient to support DV boundary formation (Milan and Cohen, 1999a). Notch activation at the DV boundary is symmetric (in contrast to the inherently asymmetric signaling from P to A cells) (**Figure 4c**). It is therefore not obvious how symmetric Notch activation could generate an affinity border. Notch signaling is required, but is not sufficient to generate a boundary without an additional Ap-dependent input. The authors envisage a permissive role for Notch activity in the DV boundary formation, with some other Ap-dependent activity providing the instructive determinant (Milan and Cohen, 2003).

1.9.2.1.3. Compartment boundaries as organizing centers Cell interactions play a critical role during development. Pioneering experiments in the frog have shown that specific groups of cells can behave as organizing centers that control the developmental fates of nearby cells in a nonautonomous manner (Spemann and Mangold, 1924). Transplantation experiments with dorsal cells from the amphibian blastopore lip showed that these cells were able to induce a complete secondary body axis when located ectopically in ventral tissue. Many developmental organizers have been found since, e.g., the notochord (inducing the floorplate) (Placzek *et al*., 1990; Yamada *et al*., 1991), the isthmic organizer between the midbrain and hindbrain (reviews: Joyner *et al*., 2000; Simeone, 2000) and the AP and DV compartment boundaries in the fly wing and leg (Diaz-Benjumea and Cohen, 1993; Struhl and Basler, 1993; Basler and Struhl, 1994) (**Figure 2c**).

In the context of compartments, formation of organizers can be separated into three steps: (1) differential cell fate specification in adjacent compartments, (2) leading to asymmetric signaling between the two cell populations, and (3) production of a symmetric organizing signal originating at the compartment boundary (Meinhardt, 1983; Struhl and Basler, 1993; Basler and Struhl, 1994; Diaz-Benjumea *et al*., 1994; Tabata and Kornberg, 1994; review: Brook *et al*., 1996).

1.9.2.1.3.1. The A–P organizer Soon after the discovery that A and P cells are separated by a lineage restriction boundary, the suggestion was made that this boundary might serve as an organizing center in the developing appendages (Crick and Lawrence, 1975). Molecular analyses revealed that specialized cells are established along the AP axis as a consequence of asymmetric signaling by the diffusible protein Hedgehog (Hh) from P to A cells (Basler and Struhl, 1994; Tabata and Kornberg, 1994) (**Figure 3b**). En generates this asymmetry by inducing expression of Hh in the posterior compartment (Tabata *et al*., 1992; Zecca *et al*., 1995) and at the same time repressing the expression of the essential downstream component Cubitus interruptus (Ci) (Eaton and Kornberg, 1990; Schwartz *et al*., 1995) (**Figure 3b**). Ci is a transcription factor that is converted to a repressor form in the absence of Hh signaling (Aza-Blanc *et al*., 1997; Méthot and Basler, 1999). Thus, only A cells that receive the Hh signal across the compartment boundary will respond by stabilization of Ci. Hh signaling leads to the expression of the secreted signaling molecule Decapentaplegic (Dpp) at the AP boundary of wing discs and of Dpp and Wg in leg discs (Struhl and Basler, 1993;

Basler and Struhl, 1994; Diaz-Benjumea *et al.*, 1994). Dpp and Wg act as symmetric long-range morphogens in wing and leg imaginal discs (Brook and Cohen, 1996; Jiang and Struhl, 1996; Lecuit *et al.*, 1996; Nellen *et al.*, 1996; Lecuit and Cohen, 1997; Entchev *et al.*, 2000; Teleman and Cohen, 2000). By this mechanism the originally asymmetric subdivision of the limb primordium eventually leads to the establishment of a symmetric organizing gradient of the morphogen (**Figure 3b**).

1.9.2.1.3.2. The DV organizer Ap expression establishes the D–V lineage restriction boundary in the wing disc (Diaz-Benjumea and Cohen, 1993; Blair *et al.*, 1994). Short-range interactions between D and V cells lead to the activation of the Notch signal transduction pathway (Diaz-Benjumea and Cohen, 1995; Kim *et al.*, 1995; Rulifson and Blair, 1995; de Celis *et al.*, 1996b; Doherty *et al.*, 1996). Notch is activated symmetrically on both sides of the DV boundary (**Figure 4c**). Ap plays an essential role in this process by inducing expression of Serrate and Fringe in dorsal cells (Irvine and Wieschaus, 1994; Speicher *et al.*, 1994; Couso *et al.*, 1995) (**Figure 5**). Serrate and the ventrally expressed Delta encode transmembrane proteins that act as ligands for the Notch receptor protein (Fleming *et al.*, 1990; Rebay *et al.*, 1991; Doherty *et al.*, 1996). Fringe modulates the sensitivity of Notch to its ligands such that Fringe-expressing cells are sensitive to Delta and refractory to Serrate (Fleming *et al.*, 1997; Johnston *et al.*, 1997; Panin *et al.*, 1997). Fringe acts in the Golgi apparatus as a glycosyltransferase enzyme that modifies the EGF modules of Notch and enhances the ability of Notch to bind to Delta (Brückner *et al.*, 2000; Moloney, 2000; Panin *et al.*, 2002). Consequently, Sersignals to V cells and Delta signals to D cells across the DV boundary. Notch is activated symmetrically and induces Wg and Vestigial (Vg) (through its boundary enhancer) on both sides of the boundary (**Figure 4c**). Wg spreads along the DV axis of the wing and further organizes growth and patterning of the wing disc (see Section 1.9.3.3) by inducing and repressing its target genes *vg* (through the quadrant enhancer), *ac–sc, Dll, fz2, and notum* in a concentration-dependent manner (Blair, 1992; Phillips and Whittle, 1993; Couso *et al.*, 1994; Zecca *et al.*, 1996; Neumann and Cohen, 1997; Cadigan *et al.*, 1998; Giraldez *et al.*, 2002) (**Figure 7**).

1.9.2.2. Nonheritable Subdivisions of Limb Primordia

Developmental boundaries exist between compartments that separate cell lineages and also between fields of cells that are subdivided less strictly. The term "territory" has been suggested for subdivisions that are not defined by lineage boundaries but are dynamically maintained by continuous signaling (Theisen *et al.*, 1996). As long as the patterning mechanisms that initiate these subdivisions continue to operate, they can define distinct domains of gene expression.

For example, local cell–cell interactions can stabilize domains of gene expression (e.g., feedback loops with neighboring cells). In these cases, the maintenance of abutting domains of gene expression will be based on position instead of cell lineage. The critical distinction is that cells in the former scenario can move between territories and change their identity accordingly. A number of noncompartmental body subdivisions in *Drosophila* are associated with specific expression of developmental genes (Williams *et al.*, 1993; Calleja *et al.*, 1996). Here the separation of the limb primordia into proximal and distal structures as one example is considered (**Figure 2a** and **b**). The wing and – more obviously so – the leg are subdivided along their proximal-distal (PD) axes into segments of morphologically distinct identity. The wing hinge, costa, and wing blade can be considered as separate "segments" (**Figure 2b**), whereas the leg is subdivided into coxa, trochanter, femur, tibia, and five tarsi (**Figure 6c**). Several genes are expressed in PD domains of the wing and leg primordia that will give rise to the distinct morphological structures in the adult described above.

1.9.2.2.1. PD patterning in the *Drosophila* leg The homeodomain proteins Homothorax (Hth) and Extradenticle (Exd) and the Zn-finger protein Teashirt (Tsh) play important roles in defining the proximal territories in legs and wing discs. In the leg, the PD axis is set up under the control of the activities of Dpp and Wg (Diaz-Benjumea *et al.*, 1994; Campbell and Tomlinson, 1995; Lecuit and Cohen, 1997) (**Figure 6a**). Hh expression in P cells induces Dpp in the dorsal anterior half and Wg in the ventral anterior half of the leg disc (Struhl and Basler, 1993; Diaz-Benjumea *et al.*, 1994). Their combined activities specify a distal region expressing Distal-less (Dll) (Cohen *et al.*, 1989; Cohen, 1990; Diaz-Benjumea *et al.*, 1994) (**Figure 6b**), in part by repressing Hth and Tsh expressions, which are both required to specify proximal fates (Abu-Shaar and Mann, 1998; Gonzalez-Crespo *et al.*, 1998; Wu and Cohen, 1999). Hth fulfills a dual role in this context: first, it suppresses the action of the Wg and Dpp pathways and, second, it activates the expression of proximal genes such as *tsh* (Abu-Shaar and

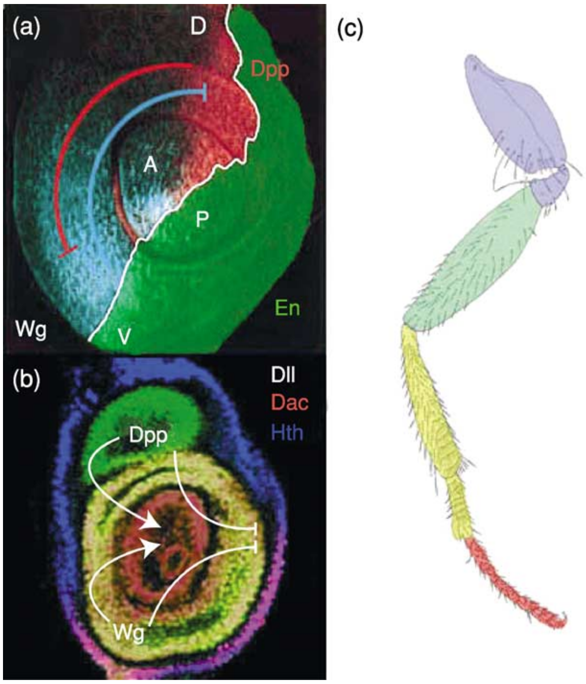

Figure 6 Proximal–distal axis formation during leg development. (a, b) Single confocal images for a third instar leg imaginal disc. (a) Wg protein (cyan) and *dpp-lacZ* (red) are activated in the anterior compartment in the ventral (V) and dorsal (D) regions respectively, by Hh signaling from the posterior compartment (green). The white line denotes the anterior–posterior (AP) boundary. Wg and Dpp repress each other's expression. (b) Wg and Dpp cooperate to activate the expression of Distalless (Dll) and Dachshund (Dac) and repress the expression of Hth. (c) Drawing of an adult leg. The colored structures correspond to the different domains of gene expression in (b).

Mann, 1998; Azpiazu and Morata, 2002). Further evidence indicates that Hth but not Tsh is essential for formation of the affinity difference between proximal and distal leg structures (Wu and Cohen, 2000) (**Figure 6b**).

The expression domain of Hth and Tsh initially forms a sharp border with more distal cells, which express Dll and later Dachshund (Dac) (Lecuit and Cohen, 1997) (**Figure 6b**). The expression domains appear to be stable but no evidence of a lineage restriction boundary can be found. Indeed, lineage tracing experiments revealed that cells born in the proximal Tsh-expressing region contribute substantially to distal territories in the leg (Weigmann and Cohen, 1999). These cells must have moved from the proximal territory into the distal territory, changing from expression of the proximal genes Tsh and Hth to expression of the distal genes Dac and Dll. These effects can be explained in terms of coupling of growth and patterning of the leg along its PD axis (Wu and Cohen, 1999, 2000). Dll-expressing cells were also shown to be able to move proximally, provided they are given a relative growth advantage (Weigmann and Cohen, 1999). Interestingly, Dll-expressing cells are able to maintain their distal identity even if Wg and Dpp signaling are inhibited, suggesting that other mechanisms besides the input of these two signals contribute to stabilization of cell fate decisions in the leg (Castelli-Gair and Akam, 1995; Lecuit and Cohen, 1997).

During the third instar, the leg disc is subdivided into presumptive segments. A number of genes expressed in rings in the leg disc prefigure segmentation of the leg (Cohen, 1993). Activation of Notch in cells at the distal end of each forming segment is clearly required for the establishment of segment boundaries, but it remains unclear how the activation of Notch is controlled by the expression of genes along the PD axis (de Celis *et al.*, 1998; Bishop *et al.*, 1999; Rauskolb and Irvine, 1999). Notch activation along the segment boundaries has a non-autonomous effect on proliferation and survival of surrounding cells (de Celis *et al.*, 1998; Kerber *et al.*, 2001). Still later, the presumptive tarsal region of the leg is further subdivided to produce the individual tarsal segments. Recently it has been shown that a gradient of EGFR activity mediated by the distal expression of its ligand Vein (Vn) and the membrane protein Rhomboid (Rho) is necessary for the patterning of these most distal elements (Campbell, 2002; Galindo *et al.*, 2002). At present it is not known how expression of the known Wg and Dpp target genes correlates with the induction of segmentation (**Figure 6**).

1.9.2.2.2. PD patterning in the *Drosophila* wing

A similar subdivision between P and D structures takes place in the wing primordium. The notum, wing hinge, costa, and wing blade are easily distinguishable morphological units (**Figure 2b**). First, the future wing field and the body wall are separated by the mutually exclusive action of Wg and EGFR signaling, respectively (see Section 1.9.2.1.1.2). Wg signaling activates transcription of the Pit, Oct, Unc (POU)-domain transcription factor *nubbin* (*nub*) and *vestigial* (*vg*) in the wing field and restricts expression of *homothorax* (*hth*), *teashirt* (*tsh*), and *vein* (*vn*) (an EGFR ligand) to the body wall (see **Figure 4a**). Later, the wing field is further subdivided into domains that will give rise to the wing blade, costa and the hinge articulating the wing with the body wall in the adult animal.

In the wing pouch, Wg and Dpp activate *vg*, which – together with *scalloped* (*sd*) – is required for growth and cell survival of wing blade cells

(Simpson and Schneiderman, 1975; Williams *et al.*, 1994; Kim *et al.*, 1996, 1997b; Halder *et al.*, 1998; Simmonds *et al.*, 1998; Liu *et al.*, 2000). Misexpression and loss-of-function analyses of Vg and Sd revealed that Vg- and Sd-dependent cell affinity differences contribute to the separation of the wing blade from the wing hinge and to a gradient of cell affinities along the PD axis of the wing (Liu *et al.*, 2000). Since Vg expression requires the continuous input of Wg and Dpp signals, the precursor cells of hinge and blade are not strictly separated by cell lineage.

The hinge is a flexible region that is required for wing flapping and for the movement of extension and flexion over the abdomen (Snodgrass, 1935). It originates from rings of tissue surrounding the wing pouch. Wg is required for costa and hinge development (Neumann and Cohen, 1996a). The regulation of Wg expression in the costa and hinge is complex and only partially understood to date. So far only the factors influencing Wg expression in the inner ring (costa) have been analyzed in detail. The *rotund (rn)* gene is a member of the Krüppel family of zinc-finger transcription factors (see **Chapter 1.8**). Loss-of-function mutations of *rn* lead to a loss of hinge structures among other phenotypes (Del Alamo Rodriguez *et al.*, 2002; St. Pierre *et al.*, 2002). Similarly, the POU-domain transcription factor Nubbin is essential for costa and hinge formation (Ng *et al.*, 1995; Del Alamo Rodriguez *et al.*, 2002). Both *rn* and *nub* are required for Wg expression in the inner ring in a cell-autonomous fashion. Vg expression in the wing pouch is essential for the activation of Wg, Rn, and Nub in the inner ring, indicating that a signal emanating from the Vg-expressing cells in the pouch contributes to patterning in the hinge. The nature of this signal remains to be determined. Interestingly, Wg and Vg coexpression is incompatible with hinge fate (Del Alamo Rodriguez *et al.*, 2002). Maintenance of Wg expression in the hinge is independent of Vg but instead requires Hth. As opposed to the wing blade, Wg activates Hth in the hinge (Azpiazu and Morata, 2000), thereby mediating *wg* autoregulation. In collaboration with Tsh this proximal expression of Hth represses Vg (Casares and Mann, 2000), thereby establishing the new hinge domain.

The notum part of the wing disc will give rise to the thorax (**Figure 2a** and **b**; blue shading). Hth expression is required for notum formation. Vg is required to repress the expression of Hth in distal wing tissue (i.e., the prospective wing blade), thus separating notum and pouch tissues. As in the distal portion of the leg, both Wg and Dpp signaling are responsible for this effect (Azpiazu and Morata, 2000). Hth and Tsh are the only markers of proximal tissue known to be common in wing and leg primordia. Nub and Dll are required for distal specification in the wing and leg, respectively. Recently, it was found that the *elbow/no ocelli* (*el/noc*) gene complex is necessary for distal specification in both wings and legs (Weihe *et al.*, 2004), providing evidence for a common molecular basis of wing and leg appendage specification.

1.9.2.2.3. Formation of vein and intervein regions Wing veins are the overt morphological readout of the AP patterning system in the adult wing (Sturtevant and Bier, 1995; de Celis, 1998; Bier, 2000; review: Milan and Cohen, 2000a). The establishment of veins and intervein regions depends on both the Hh and Dpp signaling pathways and represents a secondary subdivision of the A and P compartments. The short-range Hh gradient positions vein three (L3) (Mullor *et al.*, 1997; Strigini and Cohen, 1997) and induces expression of the EGFR ligand Vein (Vn), which is in turn required for the establishment of vein four (L4) in nearby P cells (García-Bellido *et al.*, 1994). Hh signaling also controls cell proliferation in this intervein territory (Duman-Scheel *et al.*, 2002).

The veins correspond to four longitudinal stripes of cells, where several genes of the EGFR (*argos, veinlet*) and Notch signaling pathways (*Delta*) are expressed. Intervein territories are characterized by the expression of Blistered (Bs), the *Drosophila* homolog of the serum response factor (SRF) transcription factor. Bs activity prevents the formation of vein tissue (Fristrom *et al.*, 1994). The Notch target gene $E(spl)m^{\beta}$ is also expressed in the intervein territories and excluded from the developing veins (review: de Celis, 1998). Dpp signaling along the AP axis leads to the activation of its target genes *spalt-major* (*salm*) and *spalt-related* (*slr*) in a broad medial domain of the wing disc (Lecuit *et al.*, 1996; Nellen *et al.*, 1996). The juxtaposition of Spalt-expressing and nonexpressing cells results in the generation of vein L2 and mutations in both genes interfere with formation of vein L5 (de Celis *et al.*, 1996a; Sturtevant *et al.*, 1997).

Differentiation of the veins occurs during the pupal stages through the action of the transcription factor Ventral veinless (Vvl) (de Celis *et al.*, 1995; de Celis and Barrio, 2000). At this stage, it is possible to distinguish a central stripe where EGFR signaling is active, and two adjacent stripes where Notch signaling is active. The cells where EGFR signaling is active will differentiate as veins in the adult wing (Gabay *et al.*, 1997). Activation of Notch in the anterior and posterior lateral stripes limits the width of the vein-forming stripe.

Interestingly, clones of genetically marked cells tend to grow within a particular intervein territory without crossing the presumptive veins (Gonzalez-Gaitan *et al*., 1994). However, if given a growth advantage over surrounding tissue, clones can cross veins, indicating that veins do not constitute lineage boundaries (Baonza and García-Bellido, 1999). Therefore, intervein regions do not qualify as compartments but are subdivisions separated by differences in gene expression. Differences in cell affinity help to maintain these subdivisions. It has been shown that Hh signaling directly influences cell affinity in the intervein territory between veins 3 and 4 (Blair and Ralston, 1997; Rodriguez and Basler, 1997; Dahmann and Basler, 2000). Activity of Spalt is involved in mediating differential cell affinity between veins 2 and 5 (Milan *et al*., 2001a).

1.9.2.2.4. Notum subdivision by Pannier and the Iroquois complex *pannier* and the genes of the *iroquois* complex (*iro*-C) are expressed in a mutually exclusive patterns in the mesothoracic part of the wing imaginal disc. Pannier confers adhesion properties that prevent medial cells from mixing with lateral cells that express Iro-C. This subdivision does not produce a cell lineage boundary (Calleja *et al*., 1996). The Iro-C complex (consisting of three related homeodomain proteins; Mirror (Mirr), Araucan (Ara), and Caupolican (Caup)) is required to specify lateral thoracic body wall (Gomez-Skarmeta and Modolell, 1996; McNeill *et al*., 1997; Cavodeassi *et al*., 2001). Early in development, Iro-C is expressed in the entire thoracic body wall due to the activity of Dpp (Cavodeassi *et al*., 2002). Cells mutant for *iro-C* transform the lateral body wall into proximal hinge structures (Diez del Corral *et al*., 1999), suggesting that the genes of the Iro-C complex fulfill selector-like roles for body wall development. Interestingly, the Iro-C complex is also required for DV specification in the developing eye and head (Dominguez and de Celis, 1998; Cavodeassi *et al*., 2000; Pichaud and Casares, 2000).

1.9.3. Morphogen Gradients and Pattern Formation

Compartment boundaries are the sources of morphogens. Morphogens are signaling molecules that are produced from a localized source forming long-range concentration gradients that pattern a field of cells (**Figure 7a**). Cells interpret their position as a function of the amount of signal they receive, thus obtaining "positional information" (Wolpert, 1989, 1996). Signaling molecules have to fulfill two stringent criteria to qualify as morphogens: (1) their effect must be exerted in a concentration-dependent manner and (2) they must act directly on target cells at a distance from the source (i.e., not through a secondary relay mechanism). When these criteria are met, the local concentration can be interpreted as a measure of distance from the source of the signal (**Figure 7a**). The three signaling proteins that qualify as morphogens in *Drosophila* wing development are Hedgehog (Hh), Decapentaplegic (Dpp), and Wingless (Wg) (e.g., Wg is shown in **Figure 7**).

It is generally accepted that cells interpret the gradient by eliciting differential transcriptional responses depending on the concentration of morphogen they are exposed to. This requires cells to make decisions depending on different threshold levels of signaling pathway activity. The concept implies that a single event – namely the production of a secreted molecule at a localized source – can lead to the formation of several different cell types in a correct spatial relationship to each other (**Figure 7**). This represents a highly efficient way of generating complex patterns in previously uncommitted cells (review: Gurdon and Bourillot, 2001).

Different modes of morphogen movement/transport have been invoked to explain long-range gradient formation: extracellular diffusion of the secreted molecule (van den Heuvel *et al*., 1989 (discussed in Lander *et al*., 2002); McDowell *et al*., 1997; Pfeiffer *et al*., 2000; Strigini and Cohen, 2000; Teleman and Cohen, 2000; Teleman *et al*., 2001), cycles of receptor-mediated endocytosis and resecretion (planar transcytosis) (Entchev *et al*., 2000; Entchev and Gonzalez-Gaitan, 2002), membranous exosomes (argosomes) (Greco *et al*., 2001), and cytoplasmic extensions (cytonemes) (Ramirez-Weber and Kornberg, 1999). Although there is no compelling evidence to date that mechanisms other than diffusion contribute productively to gradient formation, it is certainly plausible that these mechanisms could do so. Cytonemes and argosomes exist, but have not yet been shown to be required to mediate ligand movement or to transduce signals. Evidence presented in favor of endocytosis and resecretion as a mechanism of ligand transport has been questioned (Lander *et al*., 2002). Further experimental evidence is needed to support or refute these possibilities.

Several factors have been implicated in shaping morphogen gradients: posttranslational modification of the ligand can influence diffusibility (e.g., acylation of Hh and Wg (Ingham, 2000, 2001)). Regulation of receptor levels can influence ligand

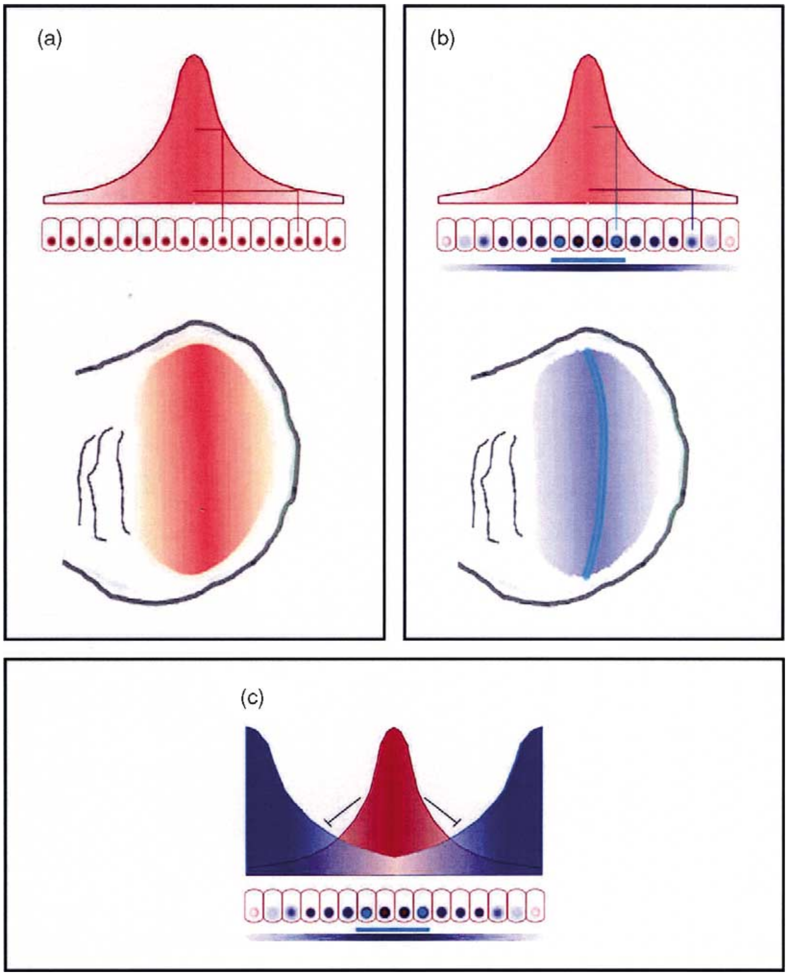

Figure 7 Example of a morphogen gradient: Wingless (Wg). (a) Drawing of a section of the wing pouch epithelium (upper panel) and of the wing pouch in an apical view (lower panel). The cells in the center express Wg which generates a gradient across the adjacent tissue. Cells at different distances receive different levels of Wg. (b) Schematic drawing of the Wg gradient and target gene activation in the epithelium in response to Wg (upper panel). The Wg gradient activates the target genes *hindsight* (cyan) and *distalless* (blue) at different threshold levels. The expression domains of Hindsight and Distalless are depicted in the same colors in the lower panel. (c) Wg downregulates its own receptor Drosophila Frizzled 2 (DFz2; blue), shaping its gradient and rendering the cells at a distance from the source of Wg more sensitive.

movement (Chen and Struhl, 1996; Cadigan *et al*., 1998; Lecuit and Cohen, 1998) (**Figure 7c**). Cell surface heparan-sulfate proteoglycans, and secreted enzymes that modify them, can modulate ligand movement (The *et al*., 1999; Baeg *et al*., 2001; Giraldez *et al*., 2002; review: Nybakken and Perrimon, 2002). Secreted ligand binding proteins can influence movement or stability (Bouwmeester *et al*., 1996; Leyns *et al*., 1997; Wang *et al*., 1997; Ashe and Levine, 1999; Ross *et al*., 2001). In addition, cellular responses to these ligands can also be modulated, contributing to shaping the activity gradients rather than the ligand gradients per se (Tsuneizumi *et al*., 1997; Teleman and Cohen, 2000; Zeng *et al*., 2000). These factors will be considered in more detail in the following sections.

1.9.3.1. Hedgehog

1.9.3.1.1. Hedgehog function The *hedgehog* (*hh*) mutant and gene were originally characterized in *Drosophila* (Nüsslein-Volhard and Wieschaus, 1980; Lee *et al*., 1992; Mohler and Vani, 1992; Tabata *et al*., 1992). Hh proteins are widely conserved within the animal kingdom. Hh signaling is involved in diverse developmental processes, and when misregulated, has been implicated in disease (review: Chuang and Kornberg, 2000) (summarized in **Figure 3b**). Loss of Hh signaling in wing discs impedes growth and patterning in both A and P compartments and gives rise to severely reduced wings (Basler and Struhl, 1994). Hh acts directly to pattern the central region of the wing (Mullor *et al*.,

1997; Strigini and Cohen, 1997). The long-range effects of reduced Hh are secondary consequences due to loss of Dpp expression along the AP compartment boundary in the wing and loss of Dpp and Wg in the leg. Ectopic expression of Hh in A cells at a distance from the AP boundary or activation of signaling by removing Hh pathway inhibitors such as patched (Ptc), protein kinase A (PKA), Costal-2 (Cos-2), or Slimb (Slmb) causes dramatic reorganization of anterior pattern. Ectopic expression of Hh can lead to complete mirror image duplication of anterior structures. This shows the importance of localized Hh signaling during wing development (Basler and Struhl, 1994; Tabata and Kornberg, 1994; Jiang and Struhl, 1995, 1998; Lepage *et al.*, 1995; Li *et al.*, 1995; Pan and Rubin, 1995; Sisson *et al.*, 1997; Theodosiou *et al.*, 1998).

Asymmetry is critical to the function of the Hh patterning system. P cells, which express Hh, are not capable of transducing the Hh signal. They do not express the transcription factor Ci (due to repression by En). Anterior cells that do not receive Hh, process the full-length activator Ci protein (Ci^{155} or Ci^{A}) into a transcriptional repressor form Ci^{75} or Ci^{R} (Aza-Blanc *et al.*, 1997). Cells close to the boundary that receive Hh input stabilize Ci^{155}, leading to the induction of Hh target genes. The distance from the Hh source determines which Hh target genes are activated (**Figure 3b**). Hh can therefore be defined as a morphogen (Strigini and Cohen, 1997). Hh regulates *dpp*, *wg, ptc, en*, and *collier (synonym: knot)* expression in a concentration-dependent manner (Basler and Struhl, 1994; Capdevila and Guerrero, 1994; Tabata and Kornberg, 1994; Chen and Struhl, 1996; Mullor *et al.*, 1997; Strigini and Cohen, 1997; Vervoort *et al.*, 1999).

1.9.3.1.2. Hedgehog production Hh protein is produced as a precursor that undergoes autoproteolytic intramolecular cleavage by an intein-like mechanism (Chang *et al.*, 1994; Lee *et al.*, 1994; Porter *et al.*, 1995). This generates a 20 kDa N terminal (Hh-N) and a 25 kDa C terminal fragment (Hh-C). The enzymatic activity required for the cleavage reaction is contained within the C terminal domain (Lee *et al.*, 1994; Porter *et al.*, 1995), while the N terminal domain accounts for all known signaling activity (Porter *et al.*, 1995). During the cleavage reaction, a cholesterol moiety is covalently attached to the C terminal part of Hh-N (Porter *et al.*, 1995). Cholesterol modification may be responsible for the observed tight cell association of Hh-N to Hh producing cells. The range over which Hh-N can move and signal is greatly extended when the cholesterol modification is prevented (Porter *et al.*, 1996; Burke *et al.*, 1999). In addition, Hh is palmitoylated at its N terminus. This lipid modification is also essential for Hh function. In the absence of the acyltransferase Skinny Hedgehog (Ski), Hh lacks the N terminal palmitate residue and cannot fulfill its embryonic and larval patterning activities (Chamoun *et al.*, 2001; Lee and Treisman, 2001).

1.9.3.1.3. Hedgehog movement How do these posttranslational modifications impact on Hh movement? The cholesterol and palmitate moieties presumably bind Hh to the cell surface and might be expected to preclude diffusion. Yet Hh protein and Hh activity can be detected many cell diameters away from the cells where it is produced (Tabata and Kornberg, 1994; Mullor *et al.*, 1997; Strigini and Cohen, 1997, 1999; Chuang and Kornberg, 2000). The release of cholesterol-modified Hh-N from the producing cells depends on the activity of the protein Dispatched (Disp) in Hh-producing cells (Burke *et al.*, 1999; Caspary *et al.*, 2002; Ma *et al.*, 2002; Pfeiffer *et al.*, 2002). The *disp* mutant cells appear to produce, process, and modify Hh normally but are unable to release Hh-N and instead accumulate the protein to high levels. Intriguingly, *disp* is predicted to encode a sterol-sensing domain (SSD)-containing 12-pass transmembrane protein with sequence homology to the Hh-binding receptor protein Ptc. Ptc has been shown to limit Hh movement, in part, by targeting Hh for internalization and degradation (Chen and Struhl, 1996; Burke *et al.*, 1999; Denef *et al.*, 2000; Incardona *et al.*, 2000, 2002). Thus, both the sending and the receiving cells require the activity of an SSD-containing protein to regulate the movement of Hh-N. Receiving cells need Ptc to sequester cholesterol modified Hh-N while sending cells need Disp to release it. How exactly Disp works in Hh release remains to be determined. It is also not known how Hh moves across tissues. This may be a case where exovesicle (argosome)-mediated movement may prove to be important.

Once Hh is released, its ability to move is influenced by heparan sulfate proteoglycans (HSPGs) (Bellaiche *et al.*, 1998; Selleck, 2000). The *tout-velu* (*ttv*) gene encodes an enzyme needed for HSPG biosynthesis and its activity is needed to allow movement of cholesterol-modified Hh-N in A cells (The *et al.*, 1999; Toyoda *et al.*, 2000). HSPGs are highly O-glycosylated proteins found abundantly at the cell surface and the extracellular matrix. HSPGs interact with a variety of extracellular proteins such as growth factors, proteases, protease inhibitors, and adhesion molecules. Through these interactions, they participate in many events

during cell adhesion, migration, proliferation, and differentiation. Biochemical analyses have indicated that Hh is a heparin-binding protein (Lee *et al*., 1994). How exactly Ttv and HSPGs affect the distribution of Hh-N is still unknown. Hh-N may require HSPGs for its stability in the extracellular space. Alternatively, binding of Hh-N to HSPGs could promote its release from producing cells, prevent its reinsertion into the membrane or its sequestration by Ptc. One could speculate that transport of lipid-modified Hh depends on a yet unidentified carrier protein able to mask the lipid moiety. The possibility of a connection between such a protein and the HSPGs remains to be explored.

1.9.3.1.4. Direct patterning activity of Hedgehog Although the largest morphological changes observed in wings lacking or ectopically activating Hh signaling are caused by changes in the expression of the Hh target gene Dpp, Hh also has a more direct effect on patterning. Hh acts directly to pattern the central region of the wing, more specifically the region between the veins 3 and 4 (Mullor *et al*., 1997; Strigini and Cohen, 1997). This short-range patterning activity of Hh is at least in part mediated through the local induction of En and the transcription factor Collier (Col) (Nestoras *et al*., 1997; Vervoort *et al*., 1999). Another important function of Hh, mediated through a Ci-dependent but thus far unidentified target gene, is preventing A and P cells from mixing, thus maintaining the AP compartment boundary (Blair and Ralston, 1997; Rodriguez and Basler, 1997; Dahmann and Basler, 2000) (**Figure 3a**).

1.9.3.2. Decapentaplegic

Decapentaplegic (Dpp) is a member of the bone morphogenetic protein (BMP) class of transforming growth factor-β (TGF-β) signaling molecules (Hoffmann and Goodman, 1987; Irish and Gelbart, 1987; Padgett *et al*., 1987; reviews: Padgett *et al*., 1998; Raftery and Sutherland, 1999; Massague and Chen, 2000). Many different biological processes are mediated by TGF-β ligands. These include the regulation of growth, differentiation, and cell fate determination. Defects in TGF-β signaling components have been implicated in a number of heritable disorders (review: Massague *et al*., 2000).

1.9.3.2.1. Dpp signaling In *Drosophila*, three BMP-like factors are known: Dpp, Glass bottom boat (Gbb), and Screw (Scw). Dpp seems to be the most important factor for limb development. TGF-β factors initiate signaling by assembling receptor complexes that activate Smad transcription factors. The ligand brings together members from two families of receptor serine/threonine kinases, known as the type I and type II receptors (reviews: Raftery and Sutherland, 1999; Massague and Chen, 2000; Massague *et al*., 2000). The principal Dpp receptors in *Drosophila* are Thickveins (Tkv) and Punt (Pnt), type I and II, respectively (Brummel *et al*., 1994; Letsou *et al*., 1995; Ruberte *et al*., 1995). Saxophone may also cooperate with Pnt to mediate Dpp signaling. The only known function of the type II receptor (Pnt) is to activate the type I receptor (Tkv). Tkv propagates the signal by phosphorylating the *Drosophila* Smad, Mad (Mothers against Dpp) (Newfeld *et al*., 1996; Wiersdorff *et al*., 1996). In addition to Mad, which belongs to the class of receptor-regulated Smads (R-Smads), Dpp signaling requires the action of the co-Smad Medea (Med) (Das *et al*., 1998; Hudson *et al*., 1998; Wisotzkey *et al*., 1998). Upon phosphorylation of Mad by Tkv, it associates with Medea and translocates into the nucleus, where the complex directly binds to DNA and regulates transcription (e.g., Kim *et al*., 1997a; review: Raftery and Sutherland, 1999). However, activation of the Dpp pathway at high levels induces the expression of an inhibitory Smad (Dad), which acts to reduce Dpp signaling activity in these cells, thereby limiting the maximal extent of pathway activation (Tsuneizumi *et al*., 1997). The transcription factor Brinker (Brk) is another antagonist that modulates cellular responsiveness to Dpp signaling. Brinker represses expression of Dpp target genes in the wing disc (Campbell and Tomlinson, 1999; Jazwinska *et al*., 1999; Minami *et al*., 1999). Interestingly, *brinker* expression is negatively regulated by Dpp, providing another level of feedback regulation.

1.9.3.2.2. Regulation of Dpp gradient formation Dpp is the main organizer of patterning along the AP axis in the wing imaginal disc. Dpp is produced by A cells adjacent the AP compartment boundary in the *Drosophila* wing (**Figure 3b**) and forms a long-range gradient that activates several target genes in a concentration-dependent manner (Lecuit *et al*., 1996; Nellen *et al*., 1996; Lecuit and Cohen, 1998; Entchev *et al*., 2000; Teleman and Cohen, 2000; Entchev and Gonzalez-Gaitan, 2002). Whether free diffusion alone can explain Dpp gradient formation remains unclear. Receptor-mediated endocytosis contributes to shaping the Dpp gradient by targeting some Dpp for degradation (Entchev *et al*., 2000; Teleman and Cohen, 2000). Downregulation of the receptor protein Tkv in response to Dpp signaling is needed to allow long-range movement of the ligand (Lecuit

and Cohen, 1998; Tanimoto *et al.*, 2000). Tkv downregulation is mediated by *mtv*, itself a target gene of En and Hh (Funakoshi *et al.*, 2001). Receptor-mediated endocytosis has also been proposed to be required for Dpp transport (Entchev *et al.*, 2000), though this proposal has been challenged (Lander *et al.*, 2002).

Different levels of Dpp signaling activity lead to further, noncompartmental, subdivision along the AP axis in the *Drosophila* wing disc. The *spalt-major* (*salm*) and *spalt-related* (*slr*) genes are expressed in broad domains centered on the AP boundary in response to Dpp signaling (de Celis *et al.*, 1996a; Lecuit *et al.*, 1996), subsequently positioning specialized cells to form the wing veins (de Celis *et al.*, 1996a; Sturtevant *et al.*, 1997). Salm and Slr regulate the expression domains of Caps and Tartan and confer a medial–lateral affinity difference that contributes to regionalization along the AP axis (Milan *et al.*, 2001a). The *optomotor blind* gene is expressed in a broader domain under Dpp control and is required for cell survival in the center of the wing disc (Grimm and Pflugfelder, 1996; Lecuit *et al.*, 1996).

1.9.3.3. Wingless

Wingless (Wg) is a member of the Wnt family of secreted glycoproteins (Rijsewijk *et al.*, 1987) and fulfills a number of roles during development. Wg forms an extracellular gradient in the wing imaginal disc (Strigini and Cohen, 2000) and activates several target genes in a concentration-dependent manner to organize the DV axis of the wing (Zecca *et al.*, 1996; Neumann and Cohen, 1997) and leg (Struhl and Basler, 1993; Brook and Cohen, 1996; Jiang and Struhl, 1996) (**Figures 4b, c, and 7**) and the PD axis in the leg (Lecuit and Cohen, 1997) (**Figure 6a**). Hence it can be defined as a morphogen. Here, the aspects of its production, secretion, and travel in the imaginal discs will be discussed. The Wg signal transduction pathway has been reviewed elsewhere (Wodarz and Nusse, 1998).

1.9.3.3.1. Wg production Wg secretion requires the activity of the gene *porcupine (por)*. Cells mutant for *por* show normal expression of the Wg protein but fail to secrete it. *por* encodes a multipass transmembrane protein with similarity to the acyltransferase ski, suggesting that Porcupine might acylate Wg (van den Heuvel *et al.*, 1993; Kadowaki *et al.*, 1996; Chamoun *et al.*, 2001; Lee and Treisman, 2001). In embryos, localized apical secretion of Wg has been shown to be important for its function (Simmonds *et al.*, 2001). It is not known whether polarized secretion is important in the imaginal discs.

1.9.3.3.2. Wg movement Diffusion of extracellular Wg protein has been shown to be sufficient for gradient formation in the wing disc (Strigini and Cohen, 2000). Mechanisms involving endocytosis/resecretion and argosomes have also been proposed to explain Wg movement. Wg secretion requires dynamin activity; however, once secreted, Wg movement does not require dynamin-mediated endocytosis/exocytosis (Strigini and Cohen, 2000). Indeeed, *dynamin* mutant cells accumulate higher than normal levels of extracellular Wg protein, suggesting that endocytosis plays an important role in shaping the gradient by removing Wg (Strigini and Cohen, 2000).

Evidence for vesicle-based transport of Wg has been presented for the embryo. Progeny of Wg-producing cells move away from the segment boundary in the embryo, allowing delayed secretion of Wg by cells at a distance from the compartment boundary where Wg mRNA is expressed (Pfeiffer *et al.*, 2000). For this reason, a membrane-tethered form of Wg is sufficient to confer a normal range of Wg signaling in the embryo. This mechanism might operate in conjunction with diffusion of secreted Wg. Endocytosis of Wg promotes its degradation in lysosomes (Dubois *et al.*, 2001). However, resecretion of Wg has also been shown to occur, raising the possibility that this mechanism may also contribute significantly to Wg movement in the embryo (Moline *et al.*, 1999; Pfeiffer *et al.*, 2002).

Another mechanism involving vesicle-mediated transport has been proposed based on the observation of Wg-containing exovesicles, called argosomes (Greco *et al.*, 2001). Argosomes were shown to move through the wing disc epithelium, showing a high degree of colocalization with Wg (review: Vincent and Magee, 2002). Despite the lack of direct evidence that these Wg-containing vesicles are required for gradient formation, it is certainly plausible that argosomes contribute to Wg movement. If Wg proves to be acylated, like Hh, argosomes may provide the means to move the lipid-modified ligand.

HSPGs also play an important role in Wg movement and signaling. HSPGs bind Wg at the cell surface and are required for cells to be Wg-responsive (Reichsman *et al.*, 1996). Genetic analysis of components of the biosynthetic pathway of proteoglycans such as Fringe connection (Frc) (Selva *et al.*, 2001), Sugarless (Sgl) (Binari *et al.*, 1997; Hacker *et al.*, 1997; Haerry *et al.*, 1997), Sulfateless (Sfl) (Lin *et al.*, 1999; Baeg *et al.*, 2001), Notum

(Gerlitz and Basler, 2002; Giraldez *et al*., 2002), and the glypican core proteins Dally and Dally-like (Dlp) (Lin *et al*., 1999; Tsuda *et al*., 1999; Baeg *et al*., 2001) revealed that they influence Wg signaling and/or movement (reviews: Bernfield *et al*., 1999; Lin and Perrimon, 2000; Perrimon and Bernfield, 2000; Selleck, 2001). It is, therefore, possible that HSPGs act as low-affinity receptors to stabilize Wg or, perhaps, as coreceptors to facilitate interaction with the signaling receptors Frizzled (Fz) and Drosophila Frizzled 2 (DFz2). Interestingly, most mutations that affect proteoglycan biosynthesis also affect other signaling molecules. Mutations in *dally* genetically interact with *dpp* (Jackson *et al*., 1997), while *sgl* and *sfl* also affect fibroblast growth factor (FGF) signaling (Lin *et al*., 1999).

The *Drosophila* Wg receptor DFz2 is downregulated in response to Wg signaling (Cadigan *et al*., 1998). This reduces the sensitivity of cells exposed to high levels of Wg and allows Wg to travel farther (**Figure 7c**). Response to Wg activity is also modulated by Wg-dependent induction of Naked (Nkd), an EF hand containing protein that serves as a signaling antagonist (Rousset *et al*., 2001, 2002; Zeng *et al*., 2000). Wg also regulates the expression of another secreted inhibitor, Notum (Giraldez *et al*., 2002). These mechanisms collaborate to fine-tune different morphogen gradients. This allows the formation of a reproducible pattern of differentiation and a constant shape and size during animal development.

1.9.4. Growth Control in *Drosophila* Limbs

The size and shape of the adult appendages are determined by the rates of cell division, growth, and death in the imaginal discs (reviews: Bryant and Simpson, 1984; Day and Lawrence, 2000). How is the final and constant size of the discs controlled during development?

1.9.4.1. Extrinsic Regulation of Size

Growth of the imaginal discs is influenced by the nutritional state of the larva. This does not influence body pattern per se, only tissue size (Johnston *et al*., 1999; Britton *et al*., 2002). One mediator of nutrition-dependent size control is the Insulin/PI3-kinase pathway (Chen *et al*., 1996; Leevers *et al*., 1996; Montagne *et al*., 1999; Weinkove *et al*., 1999; Britton *et al*., 2002; Ikeya *et al*., 2002; Oldham *et al*., 2002; reviews: Edgar, 1999; Oldham *et al*., 2000). In addition to insulin, PI3-kinase signaling can be activated by other growth factors and cytokines. PI3-kinase signaling influences the protein biosynthetic capacity of cells by activation of S6-kinase (S6K, the kinase that phosphorylates 40S ribosomal protein S6) (Montagne *et al*., 1999; Thomas, 2002). Activation of target of rapamycin (TOR) signaling is also dependent on nutritional conditions and also directly influences S6K through a parallel, insulin-independent pathway (reviews: Gingras *et al*., 2001; Oldham and Hafen, 2003). TOR-dependent activation of S6K results in direct activation of translation initiation factors and upregulation of a subset of ribosomal RNAs (Jefferies *et al*., 1997; Dennis *et al*., 1999; Meyuhas and Hornstein, 2000).

Thus, nutrition-dependent growth control by different pathways seems to be integrated by the regulation of S6K. These two pathways seem to be linked through the action of the *tuberous sclerosis complex* (*tsc*) genes. Tsc1 and Tsc2 form a complex that inhibits TOR, preventing growth-dependent protein synthesis. In the presence of growth factors, PI3-kinase signaling results in the phosphorylation of Tsc1 and Tsc2. This relieves inhibition of TOR and stimulates protein synthesis (Inoki *et al*., 2002; Manning *et al*., 2002; review: Marygold and Leevers, 2002).

1.9.4.2. Intrinsic Regulation of Size

During development, growth and patterning appear to be tightly linked. By and large patterning appears to determine growth and not vice versa (review: Day and Lawrence, 2000) but there are clear exceptions (Teleman and Cohen, 2000). One view is that size is specified by morphogen gradients emanating from the compartment boundaries (Lawrence and Struhl, 1996; Serrano and O'Farrell, 1997). Clearly, Wg and Dpp signaling are capable of inducing growth and cell cycle progression in a context-dependent manner (Nellen *et al*., 1996; Neumann and Cohen, 1996b, 1997; Martin-Castellanos and Edgar, 2002). However, morphogens cannot simply act as mitogens because they persist within the limb primordium, even after the organ has reached its final size, and proliferation rates do not correlate simply with proximity to the signaling centers.

The polar coordinate model (French *et al*., 1976; Bryant and Simpson, 1984) proposed an explanation by suggesting that growth stops once the set of positional values produced by the morphogen gradients is completed: juxtaposition of cells with disparate positional values triggering growth and intercalation. ("Intercalation" is a term used to indicate the insertion or introduction of anything among others; in this case introduction of structures of

intermediate positional value.) Experimentally induced discontinuities in positional values would be expected to result in intercalary growth. This was certainly the case when discontinuities were generated by surgical removal of a fragment of an imaginal disc leading to regeneration. However, when positional discontinuities were produced by genetic mosaics, no interacalary growth or patterning was observed. For example, clones of cells expressing activated components of morphogen signaling pathways (such as the activated form of the Dpp receptor Tkv) do not trigger intercalary cell proliferation or patterning whereas clones expressing the secreted signaling proteins do so (Lecuit *et al*., 1996; Nellen *et al*., 1996). Overexpression of Dpp in patterns expected to abolish the gradients also fail to block growth. Thus, there is compelling evidence against the idea that growth is driven by intercalation of missing positional values.

Detailed analyses of cell proliferation patterns and cell lineage analysis using X-ray induced clones during larval development have shown no correlation between growth, division, and the distance of a cell from the compartment boundaries (Gonzalez-Gaitan *et al*., 1994; Milan *et al*., 1996). Groups of neighboring cells divide synchronously with respect to their cell cycle stage; these groups are located at random positions throughout the wing anlage. The evidence currently available suggests that morphogen gradients are read out at quite low spatial resolution. Noncompartmental subdivisions of both wings and legs (e.g., wing interveins or leg segments) behave as semiautonomous units of growth control (review: Milan and Cohen, 2000a). Thus, elimination of a vein or a leg joint causes a reduction in size of the two adjacent intervein or leg segments territories to that of a single one (de Celis *et al*., 1996a; de Celis, 1998). There is no strong effect on the size of surrounding territories. These observations are difficult to reconcile with a model in which the morphogen gradients directly control final wing or leg size. Rather, they suggest that continuous subdivision of the limb primordia into smaller territories may be an important intermediate step in the growth regulation process.

An alternative to the polar coordinate model, the Entelechia model, has been proposed by Antonio García-Bellido (García-Bellido and de Celis, 1992; García-Bellido and García-Bellido, 1998). According to this model, cell proliferation is driven by differences in the activity of certain genes ("Martial genes"). Although the nature of these genes is not defined, it is assumed that the level of their activity can be communicated to neighboring cells, so that differences in level can trigger division of nearby cells. It is assumed in the model that the level of Martial genes is increased in the daughter cells, thus leading to a propagation of a wave of cell division across the tissue. An initial asymmetry in the activity levels of Martial genes is needed to trigger the process. This is envisaged to result from differences in cells on opposite sides of compartment boundaries. Cell proliferation stops when the differences between cells fall below detection thresholds, thus reaching the Entelechia condition ("Entelechia": Aristotelian term for completion or perfection). This self-assembly model explains how short-range cell interactions control final organ size, independently of morphogen gradients. Although logically consistent, this model is quite abstract. It is not evident what sort of signals could propagate across the epithelium. The basic premise that proliferation in one group of cells should drive a wave of proliferation that travels across the tissue is, in principle, testable using genetic mosaics.

Yet there is evidence that molecules involved in patterning such as Notch, Wg, and Dpp can drive cell proliferation. Overactivation of Dpp signaling causes accelerated wing cell growth and cell cycle progression in a coordinated way (Martin-Castellanos and Edgar, 2002). Experimental removal of Dpp, alternatively, leads to undergrowth (Burke and Basler, 1996; Kim *et al*., 1996). It has been suggested that Dpp acts as a survival factor and that its loss eventually results in removal of tissue from the epithelium by apoptosis (Moreno *et al*., 2002). Thus, while patterning molecules have been shown to influence cell proliferation, their role is more likely to be of permissive than of instructive nature.

1.9.5. Evolutionary Conservation of Limb Development

Vertebrate limb development has also been extensively studied because it provides an excellent experimental model to study the cellular and molecular mechanisms that regulate pattern formation during embryogenesis. A combination of classical embryological studies, ectopic expression analyses in the chick embryo, and gene disruption in the mouse has contributed to understanding how growth and patterning are controlled in the vertebrate limb bud (reviews: Johnson and Tabin, 1997; Schwabe *et al*., 1998; Capdevila and Izpisua Belmonte, 2001; Tickle and Munsterberg, 2001). There is ample evidence now that similar genes are involved in both vertebrate and invertebrate appendage formations. Does that mean that vertebrate and invertebrate limbs are homologous structures? Since molecular

tools have become available, a more rigorous examination of the evolutionary conservation of limb development is possible. In this section, a brief review is done on the mechanisms underlying vertebrate appendage development and compare them with invertebrate limb development, as exemplified by *Drosophila*.

The limb primordium (limb bud) is composed of mesenchymal cells derived from the somatic portion of the lateral plate mesoderm (LPM) and is covered by a layer of ectoderm (**Figure 8**). It appears at specific locations along the body axis of the developing embryo and will grow out of the body wall to form the limb. Interactions between the mesenchyme and the ectoderm coordinate growth and patterning of the primordium through the activity of organizing centers such as the apical ectodermal ridge (AER) and the zone of polarizing activity (ZPA).

1.9.5.1. Initiation of Limb Budding

The mechanisms that allocate the limb fields within the lateral plate mesoderm are still a matter of debate. It has been suggested that the establishment of overlapping domains of *Hox* gene expression prepatterns the embryonic flank at specific positions for limb induction. This proposal is based on Hox expression patterns; no functional studies have been performed to date (Oliver *et al.*, 1990; Rancourt *et al.*, 1995).

The onset of limb bud formation is marked by a bulge in the lateral wall of the embryo. It results from the continuous proliferation of cells in the prospective limb-forming region and a concomitant decrease in cell proliferation elsewhere along the length of the LPM (Searls and Janners, 1971). Signaling mechanisms that mediate directional transfer of information between different tissues such as the intermediate mesoderm (IM), the LPM, and the surface ectoderm are involved in initiation of the limb bud. It is not entirely clear, to date, which factors are responsible for induction of limb outgrowth. One mesenchymal signal that is essential for limb outgrowth is the product of the *Fgf10* gene (**Figure 8a** and **b**). Fgf10 is a member of the FGF family of secreted proteins that signal by binding to high-affinity cell surface receptors (FGFRs), thereby activating intracellular signaling pathways including the RAS-MAPK pathway. Fgf10 is initially widely expressed in the LPM but at the stage of limb initiation is restricted to the prospective limb regions. Both loss-of-function and gain-of-function analyses have shown that Fgf10 is a key factor in limb bud initiation (Ohuchi *et al.*, 1997; Min *et al.*, 1998; Sekine *et al.*, 1999). What induces Fgf10 in the LPM is unclear, though. Fgf8 expressed in the intermediate mesoderm was originally proposed to mediate limb outgrowth by inducing Fgf10 (e.g., Cohn *et al.*, 1995). The juxtaposition of IM and LPM was considered to be essential for this process, since ablation of the mesonephritic mesoderm by laser microsurgery abolished limb development (Geduspan and Solursh, 1992). However, genetic evidence for a role of Fgf8 in the IM for limb field formation is lacking. Recently it has been reported that Wnt-2b and Wnt-8c (like Wg members of the Wnt family of secreted signaling molecules) control Fgf10 expression in the chick forelimb and hindlimb, respectively (Kawakami *et al.*, 2001; Ng *et al.*, 2002; review: Martin, 2001) (**Figure 8a**). Whether or not this signal emanates from the IM and if other axial structures like the embryonic organizer (Hensen's node) or the somites are required for limb field initiation remains unclear.

1.9.5.2. Induction of the AER and Limb Outgrowth

Shortly after the limb bud first becomes visible, changes in cell shape within the surface ectoderm result in the appearance of a ridge that runs along the distal margin of each limb bud (**Figure 8c**). Once this AER has formed, the limb bud elongates along its PD axis, flattens along its DV axis, and becomes asymmetric along its AP axis. AER formation is a critical event because it produces signals that organize limb development (review: Capdevila and Izpisua Belmonte, 2001). The integrity of the AER is essential for continued cell proliferation after initiation of limb budding (Todt and Fallon, 1984). Surgical removal of the AER results in limb truncation at any time during development.

Several genes expressed in the surface ectoderm already show a DV asymmetry prior to AER induction, e.g., Radical fringe (Rfng) and En-1 (one of the vertebrate *engrailed* homologs). Rfng is expressed in the dorsal ectoderm (Laufer *et al.*, 1997; Rodriguez-Esteban *et al.*, 1997), whereas En-1 is expressed exclusively in ventral cells (Davis and Joyner, 1988). The AER forms right at the interface between the Rfng expressing and nonexpressing cells, En-1 ensuring repression of Rfng ventrally. Through this mechanism, a sharp boundary is maintained. Ectopic expression of En-1 in dorsal cells was reported to repress Rfng in the chick embryo and to induce ectopic AERs and outgrowths, showing that the juxtaposition of Rfng positive and negative cells is able to set up the AER (Laufer *et al.*, 1997; Rodriguez-Esteban *et al.*, 1997). However, *Rfng*$^{-/-}$ mice show normal limb development (Moran *et al.*, 1999b). Functional redundancy with

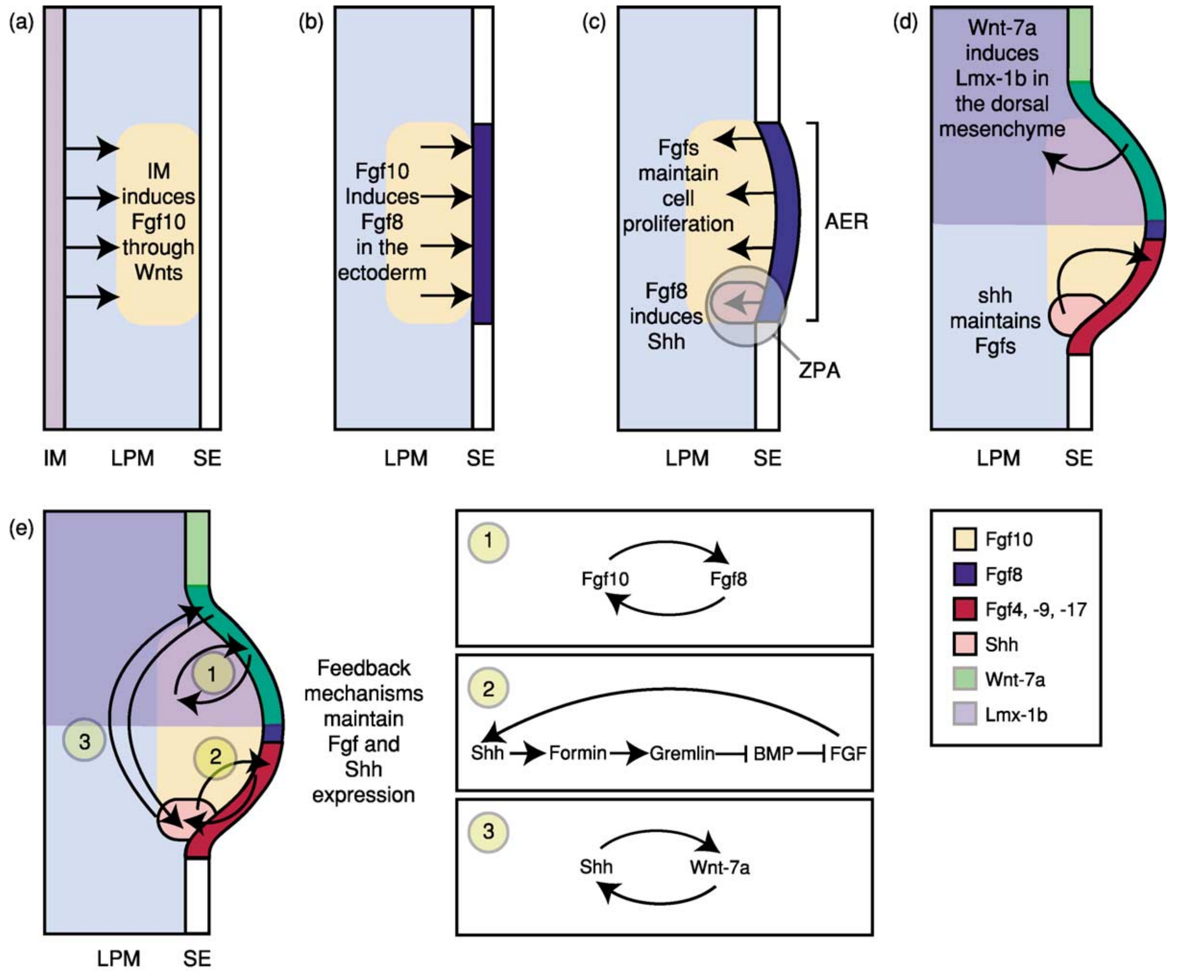

Figure 8 Vertebrate limb development. (a) Signaling from the intermediate mesoderm (IM) involving members of the Wnt family induces expression of Fgf10 in the lateral plate mesoderm (LPM). (b) Lateral plate Fgf10 induces Fgf8 expression in the surface ectoderm (SE), establishing the apical ectodermal ridge (AER). (c) Fgf signaling from the AER maintains cell proliferation in the underlying mesenchyme. Fgf8 signaling from the AER induces the expression of Sonic hedgehog (Shh) in the ventral mesenchyme, establishing the zone of polarizing activity (ZPA). (d) Shh signaling maintains Fgf signaling in the AER. Wnt-7a signaling induces the expression of Lmx-1b in the dorsal mesenchyme, where it is essential for dorsal specification. (e) Three feedback mechanisms maintain coordinate activity of the organization of three body axes. Fgf10 and Fgf8 maintain cell proliferation in the mesoderm, ensuring proper development of the proximal–distal axis. Fgf signaling from the AER maintains Shh in the ZPA. Wnt signaling from the dorsal ectoderm is required for Shh maintenance in the ZPA. The ZPA is the integration point for axis coordination in the vertebrate limb. Details of the autoregulatory loops 1–3 are shown at right.

other Rfng homologs (Lunatic Fringe and Manic Fringe) is unlikely, because expression of neither of them was detectable in the limb primordium (Johnston *et al*., 1997; Moran *et al*., 1999a). Whether these apparently contradictory results can be explained in terms of differences between the mouse and the chicken remains to be determined.

Fgf10 signaling from the LPM to the somatic ectoderm is essential for AER formation. It has been proposed that Fgf10 may be the mesenchymal mediator of the limb induction signal and thus function as the endogenous inducer of Fgf8 expression in the overlying ectoderm (Ohuchi *et al*., 1997) (**Figure 8b**). Fgf8 signaling from the AER is, in turn, essential for normal limb development (Lewandoski *et al*., 2000; Moon and Capecchi, 2000). Maintenance of Fgf10 expression in the limb bud mesoderm and Fgf8 expression in the AER is most likely dependent on a mutual positive feedback mechanism (**Figure 8c** and **d**). Recently it has been demonstrated that Wnt-3a is required for this Fgf8/Fgf10 loop to be sustained (Kawakami *et al*., 2001; Barrow *et al*., 2003). Interestingly, ablation of the AER can be rescued by artificial expression of Fgf2, Fgf4, or Fgf8 (Niswander *et al*., 1993). These factors are also capable of inducing an ectopic AER and any of them can sustain the AER's morphogenetic functions. Their redundancy can be explained by the

fact that they signal through the same FGFR (Fgf1c) in the mesoderm. Hindlimb buds of mice lacking both Fgf4 and Fgf8 do not develop a proper limb. However, since limb buds initially form, they are not required for AER formation but are essential for the expression of numerous genes in the underlying mesenchyme (e.g., Sonic hedgehog (Shh)) (Sun *et al.*, 2002). Taken together, Fgfs mediate the function of the AER in terms of limb outgrowth. They stimulate cell proliferation in the underlying mesoderm and are required to maintain Shh expression (see Section 1.9.5.4).

1.9.5.3. DV Patterning

The actual patterning of the outgrowing limb bud is tightly linked to the positioning of the AER itself (see Section 1.9.5.2). Many structures of the fully grown vertebrate limb show DV asymmetry, like tendons, bones, and muscles. Early transplantation experiments suggested that signaling from the dorsal non-ridge ectoderm is responsible for the establishment of DV asymmetry in the limb (MacCabe *et al.*, 1974). One of the signaling molecules responsible for dorsal patterning is Wnt-7a, which induces the LIM-homeodomain transcription factor Lmx-1b in the dorsal mesenchyme. Lmx-1b then specifies dorsal identities in the limb (Parr and McMahon, 1995; Riddle *et al.*, 1995; Vogel *et al.*, 1995; Chen *et al.*, 1998; review: Chen and Johnson, 1999) (**Figure 8d**). En-1 acts as a ventralizing factor and is required for repression of Wnt-7a in the ventral ectoderm (Loomis *et al.*, 1998). BMPs are necessary and sufficient to regulate the ventral expression of En-1 and are therefore required for DV patterning of the limb (Ahn *et al.*, 2001; Pizette *et al.*, 2001).

1.9.5.4. The ZPA as the Organizer of AP Polarity

In addition to DV polarity, the vertebrate limb obviously has an AP asymmetry axis as evident in muscles, bones, and tendons. Growth and patterning along the AP axis is tightly linked with development of the PD axis. This process is controlled by an interplay between the AP organizer (the ZPA) and the AER.

The ZPA is a group of cells in the posterior mesenchyme of the limb bud and its effects have been shown to be mediated by Shh (Riddle *et al.*, 1993; Chang *et al.*, 1994; Lopez-Martinez *et al.*, 1995; (**Figure 8c and d**). Shh is a homolog of the *Drosophila* secreted signaling molecule Hedgehog (see Section 1.9.3.1). While Shh is not required to establish initial AP polarity, it is absolutely essential for growth and patterning of intermediate and distal elements of the limb, and is the only factor known to date to mediate the effects of the ZPA. Shh expression is dependent on retinoic acid (RA) signaling (Helms *et al.*, 1996) and also requires AER signals, which restrict it to distal regions (Niswander *et al.*, 1994). In turn, Shh is also required for AER maintenance. Continuous Fgf signaling in the AER (which positively feeds back on Shh maintenance) depends on the limitation of BMP signaling from the underlying mesoderm (Pizette and Niswander, 1999). This effect has been proposed to be mediated by Shh through the BMP antagonist Gremlin (Capdevila *et al.*, 1999; Merino *et al.*, 1999; Zuniga *et al.*, 1999). The specification and maintenance of the AP and PD axes are tightly linked through this mechanism.

Furthermore, Shh expression is dependent on Wnt-7a signaling from the dorsal ectoderm (Yang and Niswander, 1995). Since Wnt-7a is also required for the establishment of dorsal fate (Parr and McMahon, 1995) (see Section 1.9.5.3), dorsal signals contribute to the regulation of AP patterning. The formation of all three axes of the limb is therefore tightly connected (**Figure 8**).

1.9.5.5. Proximal Patterning of the Vertebrate Limb

Interestingly, proximal patterning in the vertebrate limb seems to be dependent on similar factors to those in *Drosophila*. The *Pbx1* and *Meis* genes (homologs of *Exd* and *Hth*, respectively) are restricted to proximal parts of the limb bud. Activity of the *Meis* genes is both necessary and sufficient to confer proximal fate, similar to the action of *Hth* in *Drosophila* (Capdevila *et al.*, 1999; Mercader *et al.*, 1999, 2000).

1.9.5.6. Compartments in the Vertebrate Limb

The vertebrate limb bud ectoderm is subdivided into compartments (review: Tickle and Munsterberg, 2001). This subdivision occurs between dorsal and ventral cells even though there is some debate about the exact position of the lineage restriction boundary. All studies agree that the boundary of the ventral compartment lies at the midpoint of the AER. Surprisingly, in some experiments, dorsal cells seem to be able to cross this boundary to fill the entire ridge in the chick (but do not move into ventral ectoderm) (Altabef *et al.*, 1997). How this result can be reconciled with the existence of the ventral lineage restriction boundary remains unclear. In the mouse, the compartment boundary within the AER is transient. Additionally, a second lineage boundary between dorsal ectoderm and the AER exists (Kimmel *et al.*, 2000).

The midpoint of the AER corresponds exactly to the En-1 expression domain. However, *En-1* is not a ventral selector gene because the lineage boundary remains intact in *En-1*$^{-/-}$ mice (Loomis *et al.*, 1996). Also, misexpression of En-1 does not perturb the boundary (Altabef *et al.*, 2000). The mechanism responsible for the establishment of compartmental subdivision in the limb bud ectoderm therefore remains to be identified. For this reason, it has not been possible to experimentally eliminate boundary formation to investigate whether the existence of the boundary is essential for AER formation.

1.9.5.7. Similarities and Differences between *Drosophila* and Vertebrate Limb Development

Both *Drosophila* and vertebrate limbs are outgrowths of the body wall. In principle, they serve the animal to fulfill similar tasks. It is obvious that some elements of the regulatory circuitry and some of the same signaling pathways are used for limb generation in different organisms. This observation raises the question of whether *Drosophila* and vertebrate limbs are truly homologous structures or whether they are merely constructed according to a different plan, but using the same toolbox. The consideration of a few examples leads us to favor the latter view.

One cause for concern is raised by the idea that a DV body axis inversion has taken place between vertebrates and invertebrates (Arendt and Nubler-Jung, 1994; 1997; Holley *et al.*, 1995; De Robertis and Sasai, 1996). Should this be the case, then dorsal and ventral should be reversed in the limbs as well. In *Drosophila*, Ap is required for establishment of the dorsal compartment. It has been suggested that two LIM-homeodomain proteins, Lhx2 and Lmx1, perform Ap-related functions in vertebrate development (Rodriguez-Esteban *et al.*, 1998; Rincon-Limas *et al.*, 1999). Lmx1 confers dorsal identity in the vertebrate limb mesenchyme but is not involved in limb outgrowth (Parr and McMahon, 1995; Riddle *et al.*, 1995; Vogel *et al.*, 1995; Chen *et al.*, 1998). If these were homologous processes, Lmx1 is expected to be ventral in the vertebrate limb. In fact, Lmx1 is not very closely related to Ap, and is much more similar to the *Drosophila* LIM-homeodomain factors Lim1 and Lim3, neither of which seems to be involved in wing development (Hobert and Westphal, 2000).

The function of Lhx2 in the vertebrate limb remains even more elusive. Lhx2 is expressed in distal mesoderm in the limb bud (Rincon-Limas *et al.*, 1999; Lu *et al.*, 2000) and has the capacity to induce Rfng in the interlimb but not in the limb field. However, no AER is induced and mice lacking functional Lhx2 do not show a limb phenotype. It was proposed that Lhx2 performs a growth function (Porter *et al.*, 1997; Rodriguez-Esteban *et al.*, 1998). One could speculate that functional redundancy with another very closely related LIM-homeodomain factor, Lhx9, could explain these observations. Lhx9 is expressed in the forelimb and hindlimb mesenchyme but no further functional data is available (Retaux *et al.*, 1999). It will, therefore, depend on careful loss-of-function analyses of Lhx2 and Lhx9 to determine whether the multiple functions of Ap in *Drosophila* wing development are performed by these proteins in the vertebrate limb.

The expression pattern of Rfng in the dorsal ectoderm (see Section 1.9.5.2) is reminiscent of the dorsal pattern of expression of Fng in the *Drosophila* wing imaginal disc. However, in contrast to *Drosophila*, there is no data that supports the role of Rfng in DV patterning of the vertebrate limb (Laufer *et al.*, 1997; Rodriguez-Esteban *et al.*, 1997). Moreover, Lhx2 and Rfng are not coexpressed under wild-type circumstances, with Lhx2 being expressed only in more distal tissues in the limb bud. Therefore, the inducibility of Rfng in the interlimb region by Lhx2 is not proof for a functional conservation between Lhx2/Rfng and Ap/Fng, respectively. Furthermore, the role of Rfng in the establishment of DV patterning and the AER remains unclear (see Section 1.9.5.2), and a functional conservation between Fng and Rfng, in terms of limb organization, appears unlikely.

Like in the *Drosophila* wing, En-1 plays an important role in vertebrate development. However, while in the *Drosophila* wing it performs the role of a selector gene for posterior patterning, in the vertebrate limb bud it acts in ventral ectoderm and, therefore, performs quite a different role than in *Drosophila*. Nonetheless Hh and Shh are both implicated in sending signals from posterior cells.

It is not obvious how one could make an argument for a homologous developmental regulatory network. Nevertheless, the same "genetic toolbox" is used in *Drosophila* limb development and in the formation of the vertebrate limb. Therefore, it seems more plausible that limbs in different organisms are not homologous as appendage structures, but are likely to have a common origin in evolution as body wall outgrow (see Panganiban *et al.*, 1997).

Appendix Genes and proteins involved in limb development

Abbreviation	*Gene or protein name*	*Function*
ac-sc	*achaete-scute complex*	Proneural genes
ap	*apterous*	Dorsal selector gene
ara	*araucan*	Part of the Iroquois complex; important for notum patterning
argos	*argos*	Component of the EGFR signal transduction pathway
bs	*blistered*	*Drosophila* homolog of the serum response factor (SRF)
BMP	Bone morphogenetic protein	Class of secreted factors important in development of fly (Dpp) and vertebrate development (e.g., BMP2, 4); belong to the transforming growth factor-β (TGF-β) family
brk	*brinker*	Antagonist of Dpp signaling
Bx	*Beadex*; synonym for *dLMO*	Antagonist of Apterous activity
caps	*capricious*	Leucine-rich-repeat (LRR) transmembrane protein involved in dorsal–ventral affinity regulation
caup	*caupolican*	Part of the Iroquois Complex; important for notum patterning
Chp	*Chip (dLDB)*	Cofactor required for Apterous activity
Ci	*Cubitus interruptus*	Transcription factor essential for Hh signal transduction
col (kn)	*collier (knot)*	*hh* target gene, required for specification of veins three and four in the wing
cos-2	*costal-2*	Component of the Hedgehog signal transduction pathway
dac	*dachshund*	Target gene of Wg and Dpp in the *Drosophila* leg
dad	*daughters against dpp*	Inhibitory Smad
dally	*dally*	Glypican core protein, related to Dally-like
dlp	*dally-like*	Glypican core protein, related to Dally
DFz2 (fz2)	*Drosophila Frizzled 2*	Wg receptor for the canonical Wg pathway
disp	*dispatched*	Transmembrane protein of the Patched (Ptc) family; required for release of cholesterol-modified Hedgehog (Hh)
Dl	*Delta*	Notch ligand
dLDB	*Drosophila LIM-domain binding*	Cofactor required for Apterous activity
Dll	*Distal-less*	Wg target gene required for distal specification of *Drosophila* legs
dLMO	*Drosophila LIM-domain only*	Antagonist of Apterous activity
Dpp	*Decapentaplegic*	TGFβ homolog; important for anterior–posterior patterning in *Drosophila* limbs
Ddyn	*dynamin*	Protein involved in formation and release of endocytic vescicles
E(spl)	*Enhancer of split*	*Notch* target gene
EGF	Epidermal growth factor	Ligand for the EGF receptor
EGFR	Epidermal growth factor receptor	Receptor tyrosine kinase
el	*elbow*	Zinc-finger transcriptional repressor, required for distal specification of both wings and legs; binds to No ocelli (Noc)
en	*engrailed*	Posterior selector gene
En-1	Engrailed 1	Vertebrate homolog of the transcriptional repressor Engrailed
Eph		Transmembrane receptor; able to signal bidirectionally
Ephrin		Ligand for the Eph receptor; able to signal bidirectionally
exd	*extradenticle*	A binding partner of Hth
FGF	Fibroblast growth factor	Class of secreted factors important in many processes of vertebrate development (e.g., Fgf8, Fgf70)
FGFR	Fibroblast growth factor receptor	Class of receptor tyrosine kinases binding to the secreted proteins of the Fgf class (with different specificities)
fng	*fringe*	Glycosyltransferase required for Notch–Delta interaction
formin	*formio*	In the context of limb development, the *ld* mutants are gain-of-function mutants that cause misexpression of *gremlin* and inhibit BMP activity. Formins were misidentified as the *ld* gene product
frc	*fringe connection*	Enzyme required for heparan-sulfate proteoglycan biosynthesis
fz	*frizzled*	Wg receptor for the planar polarity pathway
gbb	*glass bottom boat*	BMP-like factor in *Drosophila*
Gremlin		BMP antagonist
hh	*hedgehog*	Morphogen important for anterior–posterior patterning in the *Drosophila* wing
hindsight	*hindsight*	Transcription factor, allelic to *pebble* (*peb*)
hth	*homothorax*	Homeodomain transcription factor; required for proximal specification of both wings and legs
inv	*invected*	Posterior selector gene, closely related to *engrailed*
Iro-C	*Iroquois Complex*	Gene complex consisting of *ara*, *caup*, and *mirr*; important for notum patterning
Lfng	Lunatic fringe	Member of the Fringe family of glycosyltransferases in vertebrates
Lhx2		Vertebrate LIM homeodomain protein
Lhx9		Vertebrate LIM homeodomain protein
Lim1		Transcription factor
Lim3		Transcription factor
Lmx1		Vertebrate LIM homeodomain protein

Continued

Appendix Continued

Abbreviation	*Gene or protein name*	*Function*
Mad	*Mothers against Dpp*	*Drosophila* SMAD, signal transducer of the Dpp pathway
med	*medea*	*Drosophila* co-SMAD
Meis		Vertebrate homolog of *hth*
Mfng	Manic fringe	Member of the Fringe family of glycosyltransferases in vertebrates
mirr	*mirror*	Part of the Iroquois Complex; important for notum patterning
msh	*muscle segment homeobox*	Transcription factor mediating dorsal wing identity
mtv	*master of Thickveins*	Downregulates the Dpp receptor Thickveins
N	*Notch*	Transmembrane receptor
nkd	*naked*	EF-hand containing protein; Wingless-antagonist
noc	*no ocelli*	Zinc-finger transcriptional repressor, required for distal specification of both wings and legs; binds to Elbow (El)
notum	*notum*	Negative regulator of *wingless*
nub	*nubbin*	POU-domain transcription factor; essential for wing and hinge development
omb	*optomotor blind*	Target gene of the Dpp pathway
Pbx1	postbithorax 1	Vertebrate homolog of *Exd*
Pc	*Polycomb*	Involved in chromatin based gene silencing
PI3K	phosphatidylinositol-3-kinase	Phosphorylates phosphatidylinositol at position 3; important mediator of insulin-dependent growth signals
PKA	Protein kinase A	Negative regulator of *hh* signaling; promotes Ci processing
pnr	*pannier*	Encoding transcription factor required for notum patterning
pnt	*punt*	Type II Dpp receptor in *Drosophila*
por	*porcupine*	Required for secretion of Wingless (Wg)
PS1	Position-specific antigen 1	Integrin-type adhesion molecule
PS2	Position-specific antigen 2	Integrin-type adhesion molecule
ptc	*patched*	Hh-receptor; transmembrane protein
Rfng	Radical fringe	Member of the Fringe family of glycosyltransferases in vertebrates
rho	*rhomboid*	Membrane protein promoting the cleavage of the membrane-anchored TGFalpha-like growth factor Spitz
rn	*rotund*	Zinc-finger transcription factor of the Krüppel family; important for hinge formation
S6K	S6 kinase saxophone	Phosphorylates the small ribosomal protein 6
scw	*screw*	BMP-like factor in *Drosophila*
sd	*scalloped*	Transcription factor required for wing development; Sd binds to Vestigial (Vg)
Ser	*Serrate*	Notch ligand
sfl	*sulfateless*	Enzyme required for heparan-sulfate proteoglycan biosynthesis
sgl	*sugarless*	Enzyme required for heparan-sulfate proteoglycan biosynthesis
Shh	Sonic hedgehog	Vertebrate homolog of the morphogen Hedgehog
ski	*skinny hedgehog*	Acyl transferase
slmb	*slimb*	Negative regulator of Hh signaling
smo	*smoothened*	Transmembrane protein; Hh pathway component
salm	*spalt-major*	Target gene of the Dpp pathway, required for vein formation in the *Drosophila* wing; highly related to and found in a complex with *spalt-related*
slr	*spalt-related*	Target gene of the Dpp pathway, required for vein formation in the wing
TGF-β	Transforming growth factor-β	Class of extracellular growth factors
tkv	*thickveins*	Type II Dpp receptor in *Drosophila*
TOR	*target of rapamycin*	Activity reflects nutritional conditions and leads to the activation of S6 kinase (S6K)
trn	*tartan*	Leucine-rich-repeat (LRR) protein involved in dorsal–ventral affinity regulation
Tsc1	*tuberous sclerosis complex 1*	Forms a complex with Tsc2; inhibits target of rapamycin (TOR) when dephosphorylated
Tsc2 (gig)	*tuberous sclerosis complex 2 (gigas)*	Forms a complex with Tsc1; inhibits target of rapamycin (TOR) when dephosphorylated
tsh	*teashirt*	Required for proximal specification of both wings and legs
ttv	*tout-velu*	Enzyme required for heparan-sulfate proteoglycan biosynthesis
trx	*trithorax*	Counteracts the silencing effects of *Pc* on chromatin to maintain gene activity
ve	*veinlet*	Same as *rhomboid*
vg	*vestigial*	Transcription factor required for wing development; Vg binds to Scalloped (Sd)
vn	*vein*	EGFR ligand
vvl	*ventral veins lacking*	Homeobox transcription factor
wg	*wingless*	Secreted signaling molecule
Wnt	Wingless-related MMTV integration site I	Secreted signaling molecules

1.10 Early Embryonic Development: Neurogenesis (CNS)

L Soustelle and A Giangrande,
Institut de Génétique et Biologie Moléculaire
et Cellulaire-CNRS, Strasbourg, France

1.10.1. Introduction

The relatively simple organization of insect embryos provides a useful model for investigating the mechanisms that generate and pattern complex nervous systems. Certain insects, such as the grasshopper, have very large embryos and easily accessible cells. This has allowed the analysis of cellular events as well as the manipulation of their nervous systems during development (Zinn and Condron, 1994; Sanchez *et al*., 1995). For a number of years, *Drosophila* has lagged behind because of its small size, compactness, and rapid development. The generation of sophisticated genetic tools, however, has made it possible to overcome these limitations. Neural precursors and their progeny have been identified in fixed and living animals, through the use of monoclonal antibodies, transgenic lines, and cellular dyes (see below). Analyzing the phenotype of gain-of-function and loss-of-function mutations of genes affecting this process has resulted in the identification of the molecular pathways that lead to nervous system differentiation. Finally, the evolutionary conservation amongst insects has made it possible to use the knowledge gained in the grasshopper in order to understand fly neural development (Anderson *et al*., 1980; Stent and Weisblat, 1985; Boyan and Ball, 1993). The combined use of these approaches has shed light on the basic cellular and molecular mechanisms underlying insect neurogenesis.

Flies display a central nervous system (CNS) that includes the ventral nerve cord (VNC) and the brain, as well as a peripheral nervous system (PNS) (reviews: Campos-Ortega, 1993; Goodman and Doe, 1993) (see **Chapters 1.11**, **1.12**, and **2.3–2.5**). PNS and CNS share most cellular and molecular developmental pathways. For the sake of simplicity, this chapter will mainly focus on the development of the VNC.

During embryogenesis, distinct neuronal cell types including motorneurons, sensory neurons, interneurons, and different types of glia are produced. The generation of neural diversity is a multistep process that requires different types of signals

(reviews: McConnell, 1995; Matsuzaki, 2000). On the one hand, neuralizing and inhibitory factors control the neural competence of large territories and the differentiation of neural precursors. On the other hand, positional cues control the type of neural precursors and, thereby, the type of neurons and glia that populate the nervous system.

1.10.2 Neural Differentiation

1.10.2.1 Neural Tissue Formation

The first step in nervous system development involves the acquisition of the neural competence. During embryonic development, two ventral territories acquire such competence, a wide one called the neuroectoderm, and a discrete one, the mesectoderm (reviews: Campos-Ortega, 1993; Goodman and Doe, 1993). The fly neuroectoderm is a heterogeneous tissue, in the sense that it gives rise to neurons, glia, and epidermis. Such heterogeneity, which is achieved via delamination of neural precursors, is a peculiarity of insect neurogenesis, since in vertebrates, the entire neural anlage invaginates, forms the neural tube, and produces neurons and glia (Doe and Smouse, 1990; Fraser, 1991; Salzberg and Bellen, 1996; Arendt and Nubler-Jung, 1999).

The mesectoderm separates the neuroectoderm from the mesoderm and is composed of two rows of VNC cells, one on each side of the embryo. Upon gastrulation, mesectodermal cells come together and align to form a single row of cells called the midline cells (review: Jacobs, 2000). The fly midline corresponds to the vertebrate floor plate and plays a role in axonal guidance.

1.10.2.1.1. The neuroectoderm In wild-type *Drosophila* embryos, the neuroectoderm becomes morphologically manifest during the initial phase of germ-band elongation. Positional information provided solely by the mother is sufficient to subdivide the embryo into three domains (ventral, lateral, and dorsal) corresponding to distinct fates (mesoderm, neuroectoderm, and nonneural ectoderm) (reviews: Rusch and Levine, 1996; Bier, 1997; Stathopoulos and Levine, 2002) (see also **Chapter 1.2**).

The Dorsal (Dl; NF-κB related) protein is distributed throughout the cytoplasm of the growing oocytes and unfertilized eggs (Steward, 1987). After fertilization, it is released from the cytoplasm and enters the nuclei in the ventral region, whereas it stays in the cytoplasm in the dorsal region (Roth *et al.*, 1989; Steward, 1989; Gay and Keith, 1990). Nuclear Dorsal is present at high levels in the ventral presumptive mesodermal cells, at intermediate levels in lateral cells comprising the neuroectoderm, and absent from cells giving rise to nonneural ectoderm (**Figure 1**) (Roth *et al.*, 1989; Steward, 1989; Govind and Steward, 1991; review: Bier, 1997). Once in the nucleus, Dorsal controls gene expression in a concentration dependent fashion. It functions as an activator of genes expressed in ventral and lateral regions of the embryo, but it also acts as a repressor of genes expressed in the dorsal region.

In ventral cells, peak levels of Dorsal activate the mesoderm-determining genes *twist* (*twi*) and *snail* (*sna*) (Jiang *et al.*, 1991; Kosman *et al.*, 1991; Rao *et al.*, 1991). Intermediate levels of Dorsal in the lateral embryonic regions activate a set of genes that initiate the differentiation of neuroectoderm (**Figure 1**). At least seven genes appear to be activated in the neuroectoderm including *rhomboid (rho)*

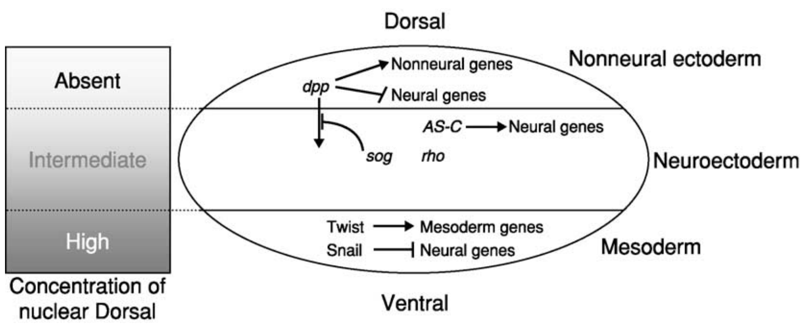

Figure 1 Dorsoventral patterning in the *Drosophila* embryo. Schematic representation of an embryo at blastoderm stage, lateral view. The molecular pathways induced by the gradient of nuclear Dorsal protein subdivide the embryo into three regions along the dorsoventral axis. High levels of nuclear Dorsal activate the expression of *twist* (*twi*) and *snail* (*sna*), which specify mesoderm identity, while intermediate levels induce *short of gastrulation* (*sog*), the *Achaete–Scute Complex* (*AS-C*), and *rhomboid* (*rho*) expression, which specify neuroectoderm identity. Absence of nuclear Dorsal activates *decapentaplegic* (*dpp*) expression. Sog prevents Dpp from signaling to the neuroectoderm and permits the expression of neural genes. (Modified from Bier, E., **1997**. Anti-neural-inhibition: a conserved mechanism for neural induction. *Cell 89*, 681–684.)

(Bier *et al*., 1990), *short gastrulation* (*sog*) (François *et al*., 1994), *lethal of scute* [*l(1)SC*] (a proneural gene belonging to the *achaete–scute* complex or *AS-C*) (Martin-Bermudo *et al*., 1995), the *m7* and *m8* genes of *the enhancer of split complex* [*E(spl)*] (Knust *et al*., 1987a), and *single-minded* (*sim*) (Kasai *et al*., 1992). Cells of the dorsal nonneural ectoderm, which contain no nuclear Dorsal, express several genes including *decapentaplegic (dpp), zerknullt (zen)*, and *tolloid (tld)* (Ip *et al*., 1991; Ray *et al*., 1991; Shimell *et al*., 1991; Huang *et al*., 1993) (**Figure 1**). In ventral and lateral cells, Dorsal represses the expression of these genes (Ray *et al*., 1991).

In vertebrates, neural tissue formation is controlled by the interplay of two types of molecules that display antagonistic functions: bone morphogenetic proteins (BMPs) and Chordin (reviews: Bier, 1997; Mehler *et al*., 1997). While BMP4 blocks the ability of ectoderm to adopt the neural fate (review: Hemmati-Brivanlou and Melton, 1997), Chordin inhibits BMP4 signaling, thereby allowing neural differentiation (Sasai *et al*., 1995; Hama and Weinstein, 2001). In *Drosophila*, *short gastrulation* (a Chordin ortholog) and *decapentaplegic* (a BMP4 ortholog) play similar roles in defining the domain of the ectoderm that will become the neuroectoderm (François and Bier, 1995; Holley *et al*., 1995; Biehs *et al*., 1996; reviews: Ferguson, 1996; Bier, 1997). Dpp is expressed in dorsal nonneural cells (Irish and Gelbart, 1987; St Johnston and Gelbart, 1987), whereas Sog is an extracellular protein expressed in the presumptive neuroectoderm (François *et al*., 1994). Both Dpp and Sog likely diffuse from their site of production into adjacent territories. In the early blastoderm embryo, Sog prevents Dpp signaling from invading the neuroectoderm (François *et al*., 1994; Biehs *et al*., 1996) (**Figure 1**). Dpp signaling functions both to maintain expression of dorsally acting genes (e.g., *zen*) and to suppress expression of genes, the so-called proneural genes, which induce the differentiation of neural precursors (Ray *et al*., 1991; Skeath *et al*., 1992; Biehs *et al*., 1996) (**Figure 1**). Complete loss of Dpp activity results in total transformation of dorsal ectoderm into neuroectoderm: both the amnioserosa (the dorsalmost region of the embryo) and the dorsal epidermis are lost in these mutant embryos (St Johnston and Gelbart, 1987). Genetic evidence supports the view that Sog opposes Dpp activity, as reducing the gene dose of *sog* rescues lethality resulting from weak mutations in the Dpp pathway (Biehs *et al*., 1996).

1.10.2.1.2. The mesectoderm In *Drosophila* embryos, the mesectoderm corresponds to a single row of cells abutting the mesoderm. Mesectoderm identity is induced by Sim, since midline cells fail to differentiate in its absence (Crews *et al*., 1988; Thomas *et al*., 1988; Nambu *et al*., 1990). The *sim* gene acts as a master gene for midline identity, as shown by the observation that its ectopic expression leads to the transformation of most lateral CNS cells into midline cells (Nambu *et al*., 1991). The *sim* gene encodes a bHLH-PAS (basic helix–loop–helix-Per-Arnt-Sim) transcription factor that heterodimerizes with the Tango (Tgo) protein (another bHLH-PAS transcription factor) to activate the expression of midline-specific genes (Sonnenfeld *et al*., 1997; Ward *et al*., 1998).

Genetic and molecular evidence indicate that *sim* expression is repressed by Snail and Suppressor of Hairless (Su(H)) in the mesoderm and the neuroectoderm, respectively (Kasai *et al*., 1992; Morel and Schweisguth, 2000). On the other hand, *sim* expression is activated by Dorsal and Twist in the cells that are located between these two territories (Kosman *et al*., 1991; Leptin, 1991; Kasai *et al*., 1992) (**Figure 2**).

The molecular mechanisms defining the mesectoderm as a single row of *sim*-expressing cells along the dorsoventral axis start being elucidated. Results from transplantation experiments indicate that cell–cell signaling between mesodermal and nonmesodermal cells is required for the early expression of *sim* (Leptin and Roth, 1994). Moreover, mesectoderm specification also involves Notch (N) activity, confirming a role of cell signaling in the regulation of *sim* expression (Menne and Klambt, 1994; Martin-Bermudo *et al*., 1995).

The current view of the Notch pathway calls for intracellular processing of Notch and formation of a complex between its intracellular domain and the Su(H) transcription factor (reviews: Jarriault *et al*., 1995; Artavanis-Tsakonas *et al*., 1999). The role of this complex is to activate the transcription of Notch responsive genes (Kidd *et al*., 1998a; Lecourtois and Schweisguth, 1998; Schroeter *et al*., 1998; Struhl and Adachi, 1998). However, recent data show that Su(H) can also act alone (Bray and Furriols, 2001). Indeed, Su(H) plays two roles: with the help of Notch, it upregulates *sim* expression in the mesectoderm, whereas it prevents *sim* expression in the neuroectoderm independently of Notch (Morel and Schweisguth, 2000).

1.10.2.2. Neural Precursor Formation

Within the neuroectoderm, also called ventral neurogenic region, nervous system development requires the activity of two classes of genes that control neural versus epidermal fate (**Figure 3**). Proneural genes promote whereas neurogenic genes inhibit neural

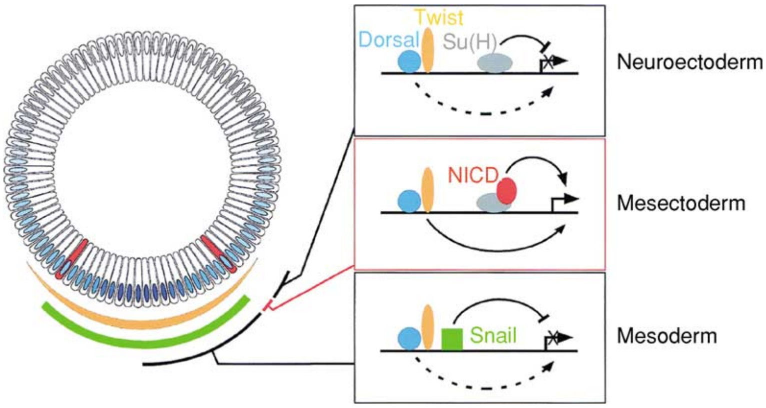

Figure 2 Molecular model for mesectoderm specification. Schematic representation of a cross-section of a fly embryo at blastoderm stage (left). In ventral nuclei, the combination of nuclear Dorsal (blue), Twist (orange), and Snail (green) transcription factors results in repression of *single-minded* (arrow at lower right). At more dorsal positions, lack of the Snail repressor as well as activation of the Notch pathway (the Notch intracellular domain (NICD) is shown in red) via the Suppressor of Hairless (Su(H)) partner and transcription factor (gray), activates mesectoderm specific genes (arrow at middle right). More dorsally, the combination of low/absent nuclear Dorsal and Su(H) dependent repression, in the absence of Notch signaling, leads to repression of *single-minded* (arrow at upper right). (Modified from Morel, V., Schweisguth, F., **2000**. Repression by suppressor of hairless and activation by Notch are required to define a single row of single-minded expressing cells in the *Drosophila* embryo. *Genes Devel. 14,* 377–388.)

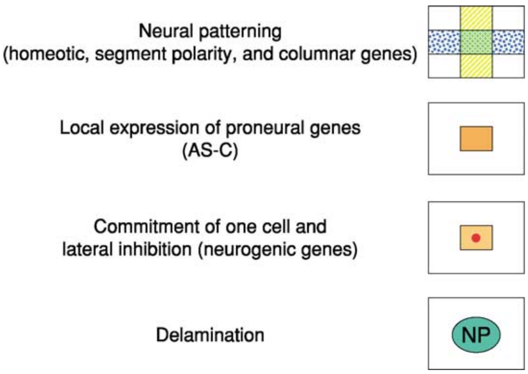

Figure 3 The neural pathway. The action of homeotic and segment polarity genes (yellow color in the first square) as well as columnar genes (blue color in the first square) subdivides the neuroectoderm in different regions along the AP and DV axis, respectively, and defines the position at which proneural clusters will be formed (green color in the first square). The expression of the *AS-C* in a cell cluster (orange rectangle) endows each cell of the cluster with the potential to become neural precursor. Progressively, due to differences in Delta expression within the cluster, the expression of the *AS-C* becomes restricted to a single cell at a stereotyped position. In all the other cells, AS-C expression progressively fades away (pale orange). The cell expressing AS-C at high levels corresponds to the presumptive neural precursor (red circle), while the adjacent ones are submitted to lateral inhibition and adopt the epidermal fate. Finally, the neural precursor (NP) emerges and delaminates from the ectoderm at a specific position, which defines the progeny of the lineage.

precursor formation, respectively (reviews: Skeath *et al.*, 1994; Hassan and Vaessin, 1996; Modolell and Campuzano, 1998; Rooke and Xu, 1998). These two gene classes act at the level of neural precursor singling out cells for delamination through a cell communication process called lateral inhibition (review: Rooke and Xu, 1998). Three steps can be recognized in this process. First, groups of cells within the neurogenic region acquire a neural competence; second, single cells within these groups become neural precursors; and third, their singling out prevents adjacent cells from taking the same fate, and leads such cells to become epidermis (review: Skeath and Carroll, 1994) (**Figures 3** and **4**).

1.10.2.2.1. Proneural genes promote neural precursor formation The classical example of proneural genes is provided by the *achaete–scute* complex (reviews: Campuzano *et al.*, 1985; Alonso and Cabrera, 1988; Campos-Ortega, 1998). Genes belonging to this complex, such as *achaete (ac), scute (sc), lethal of scute, asense (ase)*, encode bHLH transcription factors that are initially expressed in groups of equivalent cells (the proneural clusters) (Cabrera *et al.*, 1987; Jimenez and Campos-Ortega, 1990; Martin-Bermudo *et al.*, 1991; review: Skeath and Carroll, 1994). The expression of the *AS-C* endows each cell of the cluster with the potential to become neural precursor. Progressively, the expression of *AS-C* genes becomes restricted to a single cell at a stereotyped position within the cluster. This cell corresponds to the presumptive neural precursor that eventually delaminates from the neuroectoderm (Cabrera, 1990; Cubas *et al.*, 1991; Martin-Bermudo *et al.*, 1991; Skeath and Carroll, 1992) (**Figures 3** and **4**).

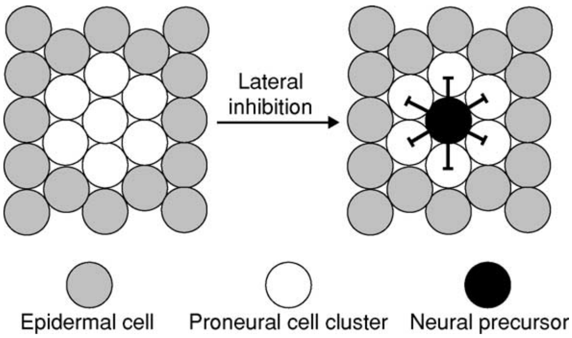

Figure 4 Lateral inhibition. Lateral inhibition is required for the selection of a single neural precursor cell during development. From a homogeneous population of epidermal cells (gray circles at left), a group of cells (the proneural cluster; white circles at left) acquires neural competence via the expression of proneural genes. Within the proneural cluster, one cell adopts the neural fate (black circle at right) due to high levels of Delta expression and thereby AS-C. This activates Notch signaling in the adjacent cells of the cluster, which inhibits AS-C expression in these cells (white circles at right). As a consequence, such cells are prevented from adopting the neural fate (black lines).

In *Drosophila*, loss-of-function analyses show that *achaete* and *scute* are required for the generation of most embryonic and adult external sense organs (Ghysen and Richelle, 1979; Jimenez and Campos-Ortega, 1990; Goriely *et al.*, 1991) (see **Chapters 1.11** and **1.12**). Similarly, gain-of-function analyses show that the *AS-C* genes are sufficient to induce the development of ectopic sensory organs at the expense of epidermis (Romani *et al.*, 1989; Rodriguez *et al.*, 1990; Dominguez and Campuzano, 1993). In the CNS, mutations in the *AS-C* lead to neural hypoplasia due to a strong reduction of the proneural cluster and the neural precursor number (Cabrera *et al.*, 1987; Dambly-Chaudière and Ghysen, 1987; Jimenez and Campos-Ortega, 1990; Cubas *et al.*, 1991; Martin-Bermudo *et al.*, 1991). As for the PNS, additional copies of *AS-C* genes cause neural hyperplasia, indicating that these genes play an instructive role in the induction of the neural fate (Jimenez and Campos-Ortega, 1990; Huang *et al.*, 1994).

Neural determination is also controlled by bHLH genes during vertebrate CNS development (reviews: Brunet and Ghysen, 1999; Bertrand *et al.*, 2002). Two gene families have been identified as being necessary for neural development: the MASH family, closely related to the *achaete–scute* genes, as well as a broad family that includes Math, Neurogenin, and NeuroD members, which are related to other bHLH *Drosophila* genes, such as *target of Poxn* (*tap*) and *atonal* (*ato*) (Jarman *et al.*, 1993; Gautier *et al.*, 1997; Kageyama *et al.*, 1997). Together with ectopic expression experiments in the ectoderm of *Xenopus* embryos, these data show that bHLH genes are necessary and sufficient to promote neurogenesis at the expense of the ectodermal fate, confirming their proneural potential (Lee *et al.*, 1995; Kim *et al.*, 1997; review: Lee, 1997).

It is interesting to note that members of the *AS-C* and *atonal* families account for all proneural activity in the fly PNS, but not in the CNS, where generation of some neural precursors does not require any of the known proneural genes. Potential bHLH candidates identified in the *Drosophila* genome are not expressed as expected for proneural factors, indicating that another family of proteins likely controls proneural activity in the fly CNS, and likely in vertebrates (Jimenez and Campos-Ortega, 1990; Moore *et al.*, 2000; Peyrefitte *et al.*, 2001). A future challenge will be to identify such proneural factors.

1.10.2.2.2. Neurogenic genes antagonize neural precursor formation Within the proneural cluster, selection of the neural precursor cell is mediated by the neurogenic genes (**Figures 3–5**). Loss-of-function mutations for such genes are characterized by nervous system hyperplasia indicating that they repress the neural fate. Neurogenic genes include those encoding the Notch receptor and its ligand Delta, as well as other genes that work in the Notch–Delta pathway (see below) (reviews: Artavanis-Tsakonas *et al.*, 1999; Baron *et al.*, 2002; Bertrand *et al.*, 2002). This pathway is involved in the process called lateral inhibition: the activation of Notch by Delta leads to receptor proteolysis (review: Chan and Jan, 1998), releasing the intracellular domain of Notch (NICD) into the cytoplasm. Then, NICD enters the nucleus and forms a complex with the Suppressor of Hairless transcription factor (**Figure 5**). Together, NICD and Su(H) activate specific targets (Bailey and Posakony, 1995) including genes of the *Enhancer of split Complex* (*E(spl)-C*), which encode transcription factors that inhibit the expression of proneural genes (Tata and Hartley, 1995; review: Bray, 1997). Since proneural genes activate Delta expression, cells in which the Notch pathway is activated eventually switch Delta expression off and adopt the epidermal fate (Kunisch *et al.*, 1994) (**Figure 5**).

The current view on the singling out of a single precursor proposes that, within the proneural cluster, all cells express proneural and neurogenic genes at similar levels. Subsequently, via mechanisms that are not understood yet, one cell of the cluster expresses more Delta than the adjacent cells. This effect is then amplified by lateral inhibition: activation of the Notch pathway in cells surrounding the presumptive neural precursor inhibits

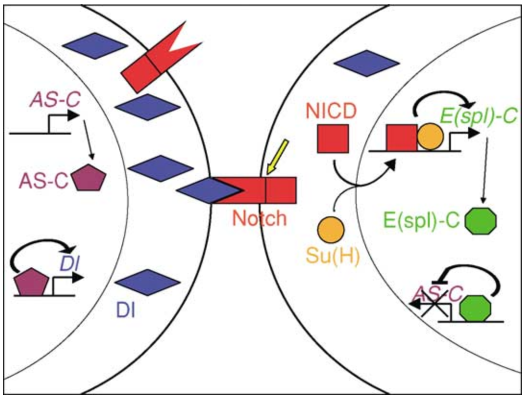

Figure 5 The Notch pathway in the proneural cluster. Thick and thin black lines indicate the cell and the nucleus membranes, respectively. Thick arrows and the T-bar indicate transcription activation and repression, respectively. Proneural genes of the *AS-C* (purple) activate Delta (Dl, blue) expression in the proneural cluster. Subsequently, one cell of the cluster (to the left) expresses more Delta than the adjacent cells (one of them is represented to the right), as simplified in the schematic drawing. Lateral inhibition entails a positive feedback loop that reinforces and maintains the initial differences between neural precursor (high Delta, cell to the left) and the other cells of the proneural cluster (low Delta, to the right). The activation of Notch (red) by Delta leads to receptor proteolysis (yellow arrow), releasing the intracellular domain of Notch (NICD, red square) into the cytoplasm. Then, NICD is transferred to the nucleus, where, together with the Suppressor of Hairless protein (Su(H), orange), it activates target genes, mainly represented by the *Enhancer of split Complex* (*E(spl)-C*, green). These target genes encode transcription factors that inhibit the expression of proneural genes (*AS-C*).

the differentiation of other neural precursors (**Figures 4** and **5**). Thus, a slight unbalance of Delta expression within the proneural cluster is sufficient to trigger a signaling pathway that allows the increase and the maintenance of AS-C and Delta expression in one cell, the neural precursor.

Mutations associated with nervous system hyperplasia permitted the identification of several other neurogenic genes, including *Enhancer of split*, *neuralized* (*neur*), *mastermind* (*mam*), *big brain* (*bib*), *almondex* (*amx*), and *neurotic* (*O-fucosyltransferase* (*O-fut1*)) (Shannon, 1972; Knust *et al.*, 1987b; Yedvobnick *et al.*, 1988; Rao *et al.*, 1990; Boulianne *et al.*, 1991; Sasamura *et al.*, 2003). All these genes modulate the Notch pathway at different steps. For example, *neurotic* encodes an O-fucosyltransferase protein that modulates the Notch–Delta interaction, and *neuralized* encodes a ubiquitin ligase that upregulates endocytosis of Delta (Boulianne *et al.*, 1991; Sasamura *et al.*, 2003). Therefore, complex gene interactions modulating the Notch pathway are involved in neurogenesis, indicating that cell–cell interactions are absolutely required to promote neural differentiation within the neuroectoderm.

1.10.2.3. Fly Neural Precursors and Lineages

1.10.2.3.1. Neuroblast lineage analysis The *Drosophila* VNC consists of a sequence of repeated units called neuromeres, each divided into two hemineuromeres separated by the midline. The singling out of the neural precursor through the interaction of neurogenic and proneural genes leads to cell delamination into a subectodermal proliferative zone. This process is achieved in five spatiotemporally distinct waves (S1–S5) to form an invariant and roughly orthogonal pattern of 30 neural precursors per hemineuromere during germ band extension (Doe, 1992) (**Figure 6**).

Three classes of neural precursors can be distinguished by the type of progeny (Bossing *et al.*, 1996; Schmidt *et al.*, 1997, 1999) (**Figure 7**). Neural precursors that give rise only to neurons or glia are called neuroblasts (NBs) or glioblasts (GBs), respectively. A third type of precursor, called neuroglioblasts (NGB), produces neurons as well as glia. The expression profile of homeotic, segment polarity and columnar genes provides a panel of specific markers for each type of neural precursor cells (Doe, 1992) (**Figure 6**). The combination of stereotyped position and gene expression is sufficient to specifically identify most neural lineages at each stage of neurogenesis. Not only is the pattern of neural precursors in each neuromere invariant, but each precursor also produces an invariant population of neurons and glia. This last feature has been revealed using lineage tracers such as 1,1′-dioctaldecyl-3,3,3′,3′-tetramethylindocarbocyanine perchlorate (DiI) and horseradish peroxidase (HRP) that allow single precursors to be followed during development (see below) (Bossing and Technau, 1994; Bossing *et al.*, 1996; Schmidt *et al.*, 1997, 1999). The simple organization as well as the stereotyped behaviors of the neural lineages have made it possible to draw a precise map of the fly embryonic nervous system

1.10.2.3.2. Types of neural precursors

1.10.2.3.2.1. The neuroblast Each hemineuromere of the ventral cord contains 23 distinct NBs, some of them specific to abdominal or thoracic segments (Bossing and Technau, 1994; Bossing *et al.*, 1996; Schmidt *et al.*, 1997, 1999; review: Van De Bor and Giangrande, 2002). After delamination, neural precursors initiate a series of asymmetric self-renewing divisions, each mitotic event generating another NB and a small cell, the ganglion mother cell (GMC), which divides once and produces two neurons (**Figure 7a**). Normarski microscopy was used to examine the morphological differentiation of a single NB in *Drosophila,* and *camera lucida*

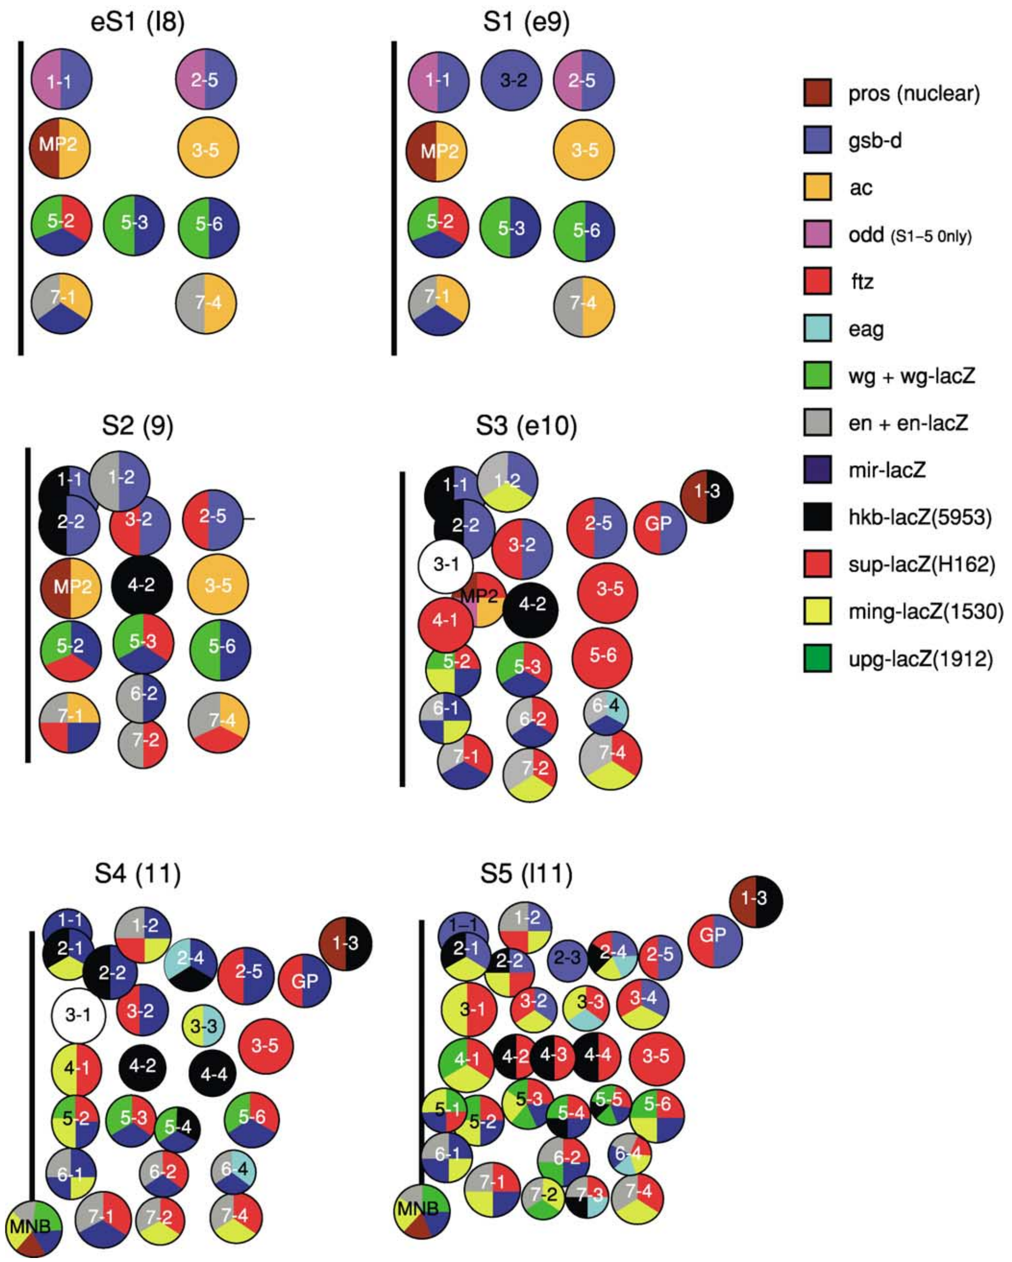

Figure 6 Identification of neuroblasts by the expression of specific molecular markers. Panels S1 to S5 indicate the five spatiotemporally distinct waves (stages are according to Campos-Ortega and Hartenstein, 1985). Numbers in brackets indicate embryonic stages, and e and l stand for early and late, respectively. In each panel, the vertical line indicates the midline. Neural precursors are distributed in seven rows (indicated by the first number in each circle) along the anteroposterior axis and five columns (indicated by the second number in each circle) along the dorsoventral axis. Each precursor is named according to its position along the axes and expresses a specific combination of molecular markers. The color coding illustrates the specific expression of the markers described at right; ac, en, wg, gsb-d, and odd represent protein markers; pros represents nuclear protein localization; eag corresponds to a mRNA pattern; wg-lacZ, en-lacZ, mir-lacZ, hkb-lacZ, svp-lacZ, ming-lacZ and upg-lacZ represent β-galactosidase staining patterns of enhancer trap lines inserted into these genes. GP, MNB, and MP2 indicate the glial precursor, median neuroblast, and midline precursor 2, respectively. The 3-1 precursor (white circle) shown in S3 and S4 does not express any of these markers. Gene abbreviations: pros (nuclear), *prospero*; gsb-d, *gooseberry-distal*; ac, *achaete*; odd, *odd-skipped*; ftz, *fushi-tarazu*; eag, *eagle*; wg and wg-lacZ, *wingless* and *wingless*-lacZ; en and en-lacZ, *engrailed* and *engrailed*-lacZ; mir-lacZ, *mirror* and *mirror*-lacZ; hkb-lacZ, *huckebein* and *huckebein*-lacZ; svp-lacZ, *seven-up* and *seven-up*-lacZ; ming-lacZ, *ming*-lacZ = *castor*-lacZ; upg-lacZ, *unplugged*-lacZ. (Modified from Hyper Neuroblast Map at http://www.neuro.uoregon.edu.)

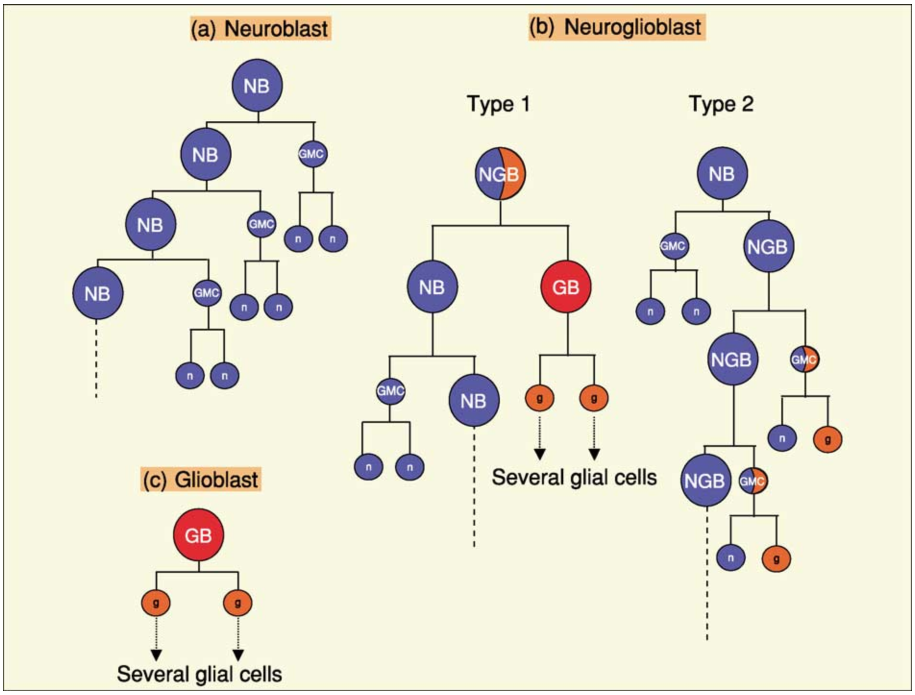

Figure 7 Types of neural precursors. Neuronal and glial potential/identities are shown in blue and red, respectively. (a) Typically, the neuroblast (NB) divides once to give rise to another NB and a small ganglion mother cell (GMC). Subsequently, the GMC divides only once to produce two neurons (n). (b) Type 1 neuroglioblast (NGB) produces restricted precursors with neuronal (NB) or glial (GB) potentials. Type 2 neuroglioblasts generate ganglion mother cells (GMCs) that produce two neurons or a glial cell (g) and a neuron. (c) Glioblasts (GB) only produce glial cells. (Modified from Van De Bor, V., Giangrande, A. **2002**. *glide/gcm*: at the crossroads between neurons and glia. *Curr. Opin. Genet. Devel. 12*, 465–472.)

tracings were used to establish the spatial relationship between NBs and GMCs (Doe, 1992). NBs form by the delamination and enlargement of individual ectodermal cells within the neurogenic region. Ectodermal cells have their nuclei localized at the ventral cell surface. When the NB forms, its nucleus moves dorsally. Soon after, this cell begins enlarging and, ultimately, delaminates from the ventral ectoderm to form a neural precursor (Doe, 1992). During NB division, a small GMC buds from its dorsal or, sometimes, lateral surface. GMCs can be molecularly identified by the presence of the Prospero (Pro) transcription factor in their nucleus (see below). This self-renewing, stem cell-like division of the NB allows the maintenance of the precursor pool and the generation of intermediate precursors, the GMCs, which have a limited proliferative potential.

1.10.2.3.2.2. The neuroglioblast (type 1 and 2) Ten NGB lineages arise from the neuroectoderm, four of them showing differences between abdominal and thoracic neuromeres (Bossing and Technau, 1994; Bossing *et al.*, 1996; Schmidt *et al.*, 1997, 1999). By lineage analysis combined with the use of molecular markers, it has been shown that at least two types of NGBs exist in *Drosophila* (Udolph *et al.*, 1993; Bernardoni *et al.*, 1999; Ragone *et al.*, 2001; review: Van De Bor and Giangrande, 2002) (**Figure 7b**). Type 1 NGB produces glial cells just after delamination upon production of a neuroblast and a glioblast, pure precursors with neuronal and glial potentials, respectively. The 6-4 lineage in the thorax (6-4T) represents an example of type 1 NGB (**Figures 7b** and **8b**; see also below). Type 2 NGB represents a variation on theme of a pure neuroblast (**Figure 8b**). It delaminates and initially produces neurons like a neuroblast. Subsequently, however, it produces GMCs that divide once and generate a neuron and a glial cell. In this case, there is no glial precursor as such. The lineage tree of type 2 NGB has been deduced through the use of mutants, genetic markers, and clonal analysis, all of which indicate that glial cells are direct siblings to neurons in this lineage and that each glial cell/neuron pair arises by asymmetric division (Udolph *et al.*, 2001). The 1-1 lineage in the abdomen represents an example of this class of NGBs (see below).

1.10.2.3.2.3. The glioblast Two GB lineages arise from the neuroectoderm (Bossing and Technau,

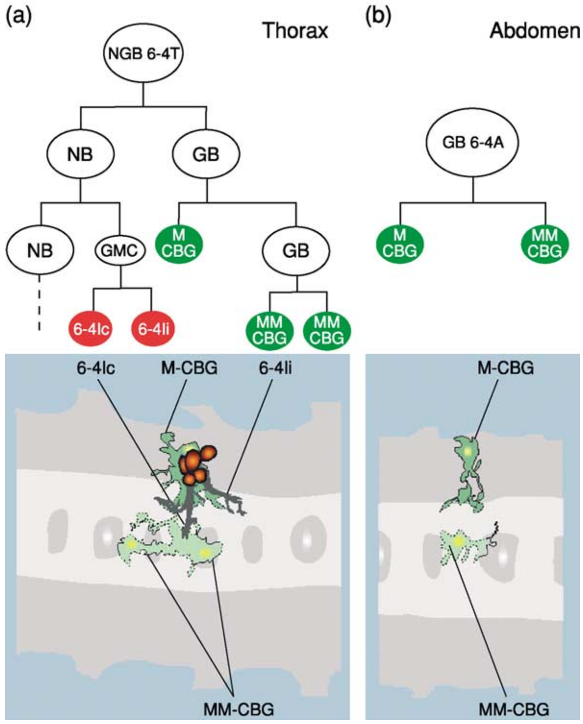

Figure 8 Drawings represent the 6-4 lineage as identified by DiI injection. The 6-4 cell produces different progenies in the thorax (a) and in the abdomen (b). (a) In the thorax, the 6-4 lineage (NGB 6-4T) gives rise to neurons (red circles) and glia (green circles). The dashed line indicates that the NB issued from the first division continues to proliferate and produces neurons, as shown by the presence of five neurons in the lower panel. (b) In the abdomen, the 6-4 lineage only produces glia (GB 6-4A). In the lower panels, cell lineages derived from 6-4 are shown in a dorsal view with anterior to the left. The cortex region and the neuropil of the ventral nerve cord are shown in gray and white, respectively. The medial dorsoventral channels, which mark the neuromere boundaries, are shown in light ovals. Clusters of neuronal cell bodies are red and their fiber projections dark gray. Glial cells are shown in green (dark and light green indicate a mediodorsal and a ventral position, respectively) and glial cell nuclei are shown in yellow. GB, glioblast; GMC, ganglion mother cell; NB, neuroblast; NGB, neuroglioblast; M-CBG, medial cell body glia; MM-CBG, medialmost cell body glia. Ic and Ii indicate interneurons (symbols are according to Bossing *et al.*, 1996).

1994; Bossing *et al.*, 1996; Schmidt *et al.*, 1997, 1999; review: Van De Bor and Giangrande, 2002). One of them is the abdominal counterpart of the thoracic 6-4 lineage (see below) and is called GB6-4A, while the other corresponds to the longitudinal glioblast. These precursors only generate glial cells (**Figure 7c**).

1.10.2.3.2.4. Midline Through the use of genetic approaches, including enhancer trap lines, in which a *LacZ* reporter gene is expressed in a lineage restricted manner, it was shown that midline neural precursors occupy a stereotyped position along the anteroposterior axis within a segment. The differentiated progeny of each precursor was then determined by morphological criteria by placing DiI on early progenitors (Bossing and Technau, 1994).

Four NB lineages arise from the posterior part of the neuromere including the midline precursors (MP), the unpaired median intermediate (UMI) precursor, the precursors of ventral unpaired median (VUM) neurons, and the median neuroblast (MNB). The precise lineage tree of all these precursors is not yet fully understood (review: Jacobs, 2000).

A pool of 10–12 midline glia (MG) precursors is localized in the anterior part of the neuromere. From this pool of precursors, only three survive by the end of embryogenesis – the anterior, the medial, and the posterior MG precursor – the others undergoing apoptosis (see below) (Klambt and Goodman, 1991; Sonnenfeld and Jacobs, 1995; Dong and Jacobs, 1997; Zhou *et al.*, 1997b).

So far, no NGB have been found in the *Drosophila* mesectoderm. Interestingly, in other insect species such as *Schistocerca americana*, a NGB differentiates at the position normally occupied by the MNB in *Drosophila* (Condron *et al.*, 1994; Condron and Zinn, 1994).

1.10.3. Neural Patterning

A total of 16 abdominal, six thoracic, and six gnathal hemineuromeres make up the VNC. At the end of neurogenesis, each neuromere contains around 400 neurons and 60 glial cells (Bossing and Technau, 1994; Bossing *et al.*, 1996; Schmidt *et al.*, 1997, 1999). The type of neurons and glial cells in these neuromeres depends on the identity of neural precursors, which we will refer to as NBs for the sake of simplicity, irrespective of whether they generate neurons or glia. Thus, it is critical to dissect the genetic regulatory mechanisms that specify the identity of individual NBs.

Studies carried out in the last 10 years indicate that many of the genes that pattern the embryo along the main axes (anteroposterior or AP, dorsoventral or DV; see **Chapters 1.2**, **1.8**, and **1.9**, also function in neurogenesis (review: Skeath, 1999). The activities of these genes create a Cartesian coordinate system that gives a unique fate to individual precursors depending on their position (review: Skeath and Thor, 2003). The invariant pattern of gene expression and progeny suggests that autonomous cues control the identity of each precursor. This is further confirmed by the observation that precursor cells keep their identity even when

cultured as isolated cells (Huff *et al.*, 1989; Broadus and Doe, 1997). One piece of evidence indicates, however, that neural precursors also display some plastic features: when late-born NBs are transplanted into early stage embryos, they acquire an early identity (Udolph *et al.*, 1995). Thus, heterochronic transplantation experiments show that neuroblast specification occurs under the control of stage-specific inductive signals that act in the neuroectoderm. Therefore, autonomous as well as nonautonomous processes appear to control precursor identity during nervous system development.

1.10.3.1. Spatial Cues Control Neuroblast Differentiation

Positional cues along the AP and DV axes allocate proper identities to different neuromeres as well as to different regions within each neuromere (**Figure 3**). Different classes of genes control the establishment of these coordinates: homeotic transcription factors define the AP identity of the different neuromeres (reviews: McGinnis and Krumlauf, 1992; Gehring, 1993; **Chapter 1.8**), whereas segment polarity and columnar genes, respectively, define the AP and the DV identities within the neuromere (review: Skeath, 1999).

1.10.3.1.1. Homeotic genes specify neuroblast identity along the AP axis The AP and DV axes of the early *Drosophila* embryo are established by two key maternal morphogens: Bicoid (Bcd) and Dorsal (Dl), respectively (Steward, 1987; Berleth *et al.*, 1988; **Chapter 1.2**). Bicoid is expressed in a broad concentration gradient along the AP axis, with peak levels present at the anterior pole, while Dorsal is expressed in a gradient along the DV axis with peak levels along the ventral surface (Ip *et al.*, 1992; **Chapter 1.2**). Both morphogens establish overlapping patterns of transcriptional activators and repressors in the early embryo, leading to expression of specific genes, including homeotic genes, which define territories along AP and DV axes (Ip *et al.*, 1992; **Chapters 1.2** and **1.8**).

The different behaviors of neural lineages between thoracic and abdominal neuromeres are explained by the expression profile of homeotic genes, which are expressed in specific domains along the rostrocaudal axis of the developing nervous system. In the fly CNS, the 1-1 lineage produces both neurons and glia in the abdomen, whereas it only produces neurons in the thorax (Udolph *et al.*, 1993; Prokop and Technau, 1994). Ultrabithorax (Ubx) and Abdominal-A (Abd-A) are not expressed in the two first thoracic segments (**Figure 9a**). It has been shown that Ubx or Abd-A misexpression in this region is sufficient to induce abdominal development of the complete 1-1 lineage

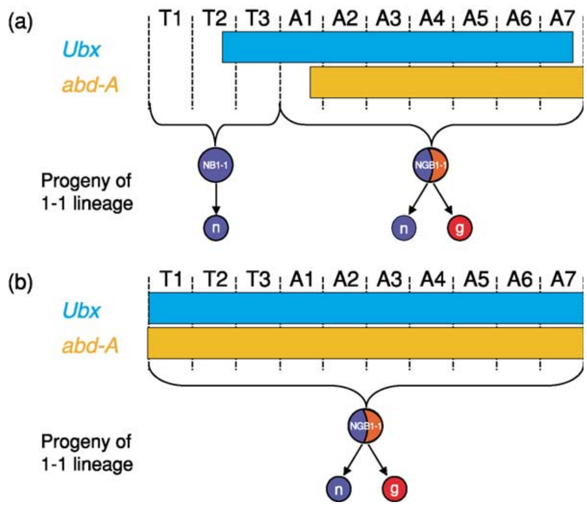

Figure 9 Homeotic genes control anteroposterior NB identity. Schematic representation of *Ultrabithorax* (*Ubx*) and *abdominal-A* (*abd-A*) gene expression domains in thoracic (T1 to T3) and abdominal (A1 to A7) neuromeres. Light blue and orange rectangles correspond to *Ubx* and *abd-A* expression domains, respectively. Anterior is to the left. Dashed vertical lines represent the boundaries of each neuromere. Blue and red indicate neuronal and glial potential/identity, respectively. (a) In wild-type embryos, *Ubx* (light blue) is expressed from T2 to A7 neuromeres whereas *abd-A* (orange) is expressed from A1 to A7. The 1-1 lineage produces both neurons (n) and glia (g) in the abdomen (NGB1-1, blue/red circle), whereas it produces only neurons in the thorax (NB1-1, blue circle). (b) When *Ubx* or *abd-A* are overexpressed in all neuromeres, the thoracic 1-1 lineage gives rise to neurons and glial cells, like in the abdomen.

and to override thoracic commitment, showing that activity of the homeotic genes *Ubx* and *abd-A* is required for abdominal specification (Prokop and Technau, 1994; **Chapter 1.8**) (**Figure 9b**).

Homeotic genes are conserved throughout evolution in their DNA binding domain (reviews: McGinnis and Krumlauf, 1992; Gehring, 1993; **Chapter 1.8**). The relative AP order of expression of *Hox* genes (the vertebrate orthologs of insect homeotic genes) in the developing vertebrate CNS is similar to the AP order of expression of homeotic genes in the *Drosophila* CNS, indicating that the role of these genes in patterning the nervous system is conserved during evolution (reviews: Boncinelli *et al.*, 1993; Krumlauf *et al.*, 1993). This is confirmed by cross-phylum gene exchange experiments showing that *Drosophila* homeotic genes can replace their vertebrate orthologs and vice versa.

While it is not clear whether *Hox* genes also control DV patterning in *Drosophila*, it has been recently shown that they do play a role in this process during vertebrate CNS development. In the mouse hindbrain, *Hoxa2* and *Hoxb2* are expressed in a pattern that defines complementary distribution along the DV axis, suggesting that these genes play a

role in DV patterning and neurogenesis (Davenne *et al.*, 1999). *Hoxa2* and double-mutant mice show DV differences in the distribution and the differentiation of early neurons, indicating a change in precursor cell identity (Davenne *et al.*, 1999). Given that nervous system development and definition of distinct neural patterns require a crosstalk between AP and DV patterning, these data suggest that, at least in vertebrates, homeotic genes integrate AP and DV positional information.

1.10.3.1.2. Segment polarity genes specify AP neuroblast differentiation and identity within the neuromere Most segment polarity genes were originally identified in the genetic screen carried out by Nüsslein-Volhard and Wieschaus (1980). The role of these genes is to subdivide each segment into an identical pattern of parallel rows. Segment polarity gene activity dissects the neuroectoderm into five transverse rows per hemineuromere and ensures that NBs that develop in different rows acquire different identities (Bhat, 1999).

Segment polarity genes include those encoding the secreted proteins Wingless (Wg) and Hedgehog (Hh), the transmembrane receptor Patched (Ptc) as well as the transcription factors Gooseberry (Gsb), Engrailed (En), and Invected (Inv) (Nüsslein-Volhard and Wieschaus, 1980; Baumgartner *et al.*, 1987; Baker, 1988; Ingham *et al.*, 1991; Mohler and Vani, 1992; Gustavson *et al.*, 1996). The expression profile of these genes subdivides the neuromere along the AP axis and spatially regulates the expression of the proneural genes *achaete* and *scute* (reviews: Skeath and Carroll, 1992, 1994). In the absence of one or more of these gene activities, a subset of proneural clusters and NBs fails to form. For example, *wg* is expressed in neuroectodermal cells that will give rise to row 5 proneural clusters, and its secreted product is also detected in adjacent rows 4 and 6 (**Figure 10**). Absence of *wg* results in a decrease of proneural cluster number in rows 4 and 6 indicating a failure in the formation of such clusters, whereas row 5 proneural clusters develop normally (Chu-LaGraff and Doe, 1993). Moreover, proneural clusters and NBs that develop in rows 4 and 6 acquire identity incorrect for their position. This indicates that *wg* promotes proneural cluster formation in rows 4 and 6 and permits them to acquire the proper identity (Chu-LaGraff and Doe, 1993) (**Figure 10**). These genes continue to be expressed in NBs, and often in their progeny, GMCs and neurons, suggesting that they play a role at later developmental stages.

Positional cues defining cell identity within the nervous system have also been identified in mesectodermal cells. In each neuromere, a single row of cells constitutes the midline cell population (review: Jacobs, 2000). The anterior midline cells produce midline glia, and the posterior ones midline neurons. Hedgehog (Hh) signaling to mesectodermal cells in the posterior domain of the neuromere is important for the determination of posterior neuronal identities. Loss of Hh results in extra midline glia (MG), because anterior lineages are duplicated when posterior identities are not specified (Hummel *et al.*, 1999a, 1999b). Conversely, expansion of Hh signaling reduces the MG number (review: Jacobs, 2000). Therefore, the Hh signaling pathway functions to determine neurons in the posterior neuromere, and is antagonistic to signals that contribute to MG identity in the anterior neuromere. Embryos mutants for *wg* and *ptc* have no anterior midline cells (including MG), indicating that *wg* and *ptc* contribute to the determination of the anterior midline identity (Zhou *et al.*, 1997a, 1997b).

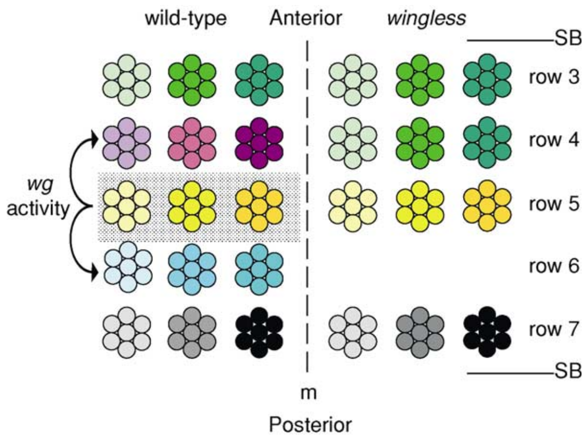

Figure 10 Segment polarity genes control NB differentiation and anteroposterior identity within the neuromere. Schematic representation of proneural clusters present within a hemineuromere of wild-type (left) or *wingless* (*wg*) (right) mutant embryos. The two hemineuromeres are separated by the midline (m, dashed line). Anterior is to the top. At this stage, five rows of clusters are present along the AP axis, called rows 3 to 7. The segment boundaries (SB) are shown by two horizontal lines. Color coding identifies specific proneural clusters along the AP and DV axes. In the wild-type embryo, Wg is expressed in row 5 (dotted pattern) and acts on adjacent rows 4 and 6 (black arrows). In the *wg* mutant embryo, proneural clusters in row 5 are still present whereas the adjacent ones are missing (row 6, absent circles) or misspecified (row 4, green circles). Row 4 switching to row 3 identity was assessed by the expression of cell specific markers in NB and GMC progeny.

1.10.3.1.3. Columnar genes specify DV neuroblast differentiation and identity within the neuromere Segment polarity gene action does not explain how NBs of the same row but different columns acquire different DV identities within the same segment.

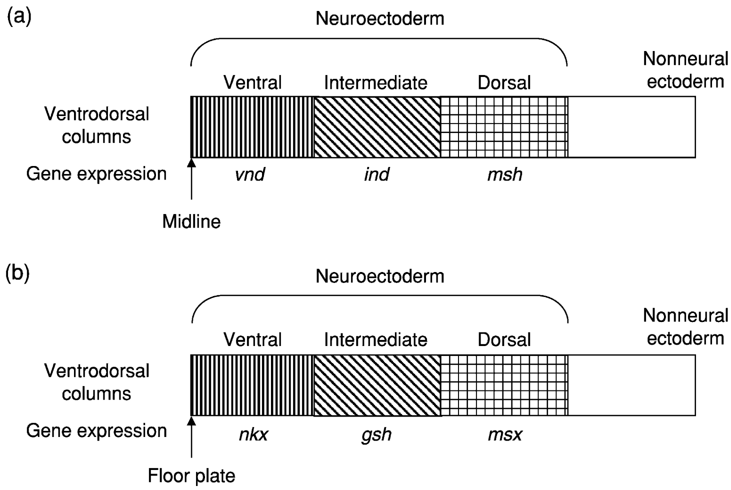

Figure 11 Evolutionary conservation of dorsoventral patterning within the neuroectoderm. Schematic representation of columnar gene expression domains in a hemineuromere of the (a) fly and (b) vertebrate neuroectoderm. Profiles of gene expression subdivide neuroectoderm into three ventrodorsal columns: *vnd/nkx*, *ind/gsh*, and *msh/msx* genes are expressed and control cell identity within ventral (vertical lines), intermediate (oblique lines), and dorsal (square motif) domains. Non neural ectoderm is indicated in white. The ventralmost position corresponds to the midline in flies and floor plate in vertebrates. (Modified from Cornell, R.A., Ohlen, T.V., **2000**. Vnd/nkx, ind/gsh, and msh/msx: conserved regulators of dorsoventral neural patterning? *Curr. Opin. Neurobiol.* 10, 63–71.)

Four factors control this process: the three transcription factors ventral nerve cord defective (Vnd) (Chu *et al.*, 1998; McDonald *et al.*, 1998), intermediate nerve cord defective (Ind) (Weiss *et al.*, 1998), and muscle segment homeobox (Msh) (Isshiki *et al.*, 1997), as well as the *Drosophila* epidermal growth factor (EGF) receptor (DER), a receptor tyrosine kinase (Livneh *et al.*, 1985; Skeath, 1998). These factors play a decisive role in dividing the neuroectoderm into three separate longitudinal regions: *vnd* is expressed in the ventral (medial) column (Mellerick and Nirenberg, 1995), *ind* is expressed in the intermediate column (Weiss *et al.*, 1998), and *msh* is expressed in the dorsal (lateral) column (D'Alessio and Frasch, 1996) (**Figure 11**). DER is expressed and required in the intermediate column to promote NB formation, and in the ventral column to specify NB identities (Yagi *et al.*, 1998). The NBs born in the dorsal column develop normally in DER mutant embryos.

Absence of columnar genes leads to defects in NB formation and to misspecification of NB identity (review: Skeath, 1999). For example, *vnd* functions in the ventral column to promote the formation of ventral identity precursors and to repress those with intermediate identity. Absence of *vnd* induces ventral cells to acquire intermediate cell identity, and *ind* expression expands into the ventral and intermediate columns (Chu *et al.*, 1998; McDonald *et al.*, 1998; Weiss *et al.*, 1998). Conversely, ubiquitous overexpression of *vnd* induces intermediate and some dorsal cells to acquire ventral identity (McDonald *et al.*, 1998). These results show that *vnd* specifies ventral column identity and prevents ventral precursors from adopting an intermediate column identity by repressing *ind*.

Elements of DV neural patterning have been evolutionarily conserved. Indeed, ortholog genes play the same role in vertebrates: the *nkx/vnd*, *Gsh-1,2/ind*, and *msx/msh* genes are expressed and control cell fates within ventral, intermediate, and dorsal domains, respectively, in the neural tube (review: Cornell and Ohlen, 2000) (**Figure 11**). It is interesting to note that upstream or downstream pathways to this "three column expression pattern" are not conserved during evolution, suggesting that this specific process plays a pivotal role in neuronal specification (review: Cornell and Ohlen, 2000).

It is also worth noting that, apart from mesectoderm-derived glia precursors, most glial precursors are localized in the dorsal part of the neuroectoderm, suggesting a role of columnar genes in the establishment of the gliogenic potential (Bossing *et al.*, 1996; Schmidt *et al.*, 1997, 1999).

A number of transcription factors such as Pannier (Pnr) and the products of the Iroquois Complex (Iro-C) have been shown to link positional cues and proneural cluster formation in the fly adult PNS (Ramain *et al.*, 1993; Leyns *et al.*, 1996; Garcia-Garcia *et al.*, 1999; Calleja *et al.*, 2000; Cavodeassi *et al.*, 2000). These transcription factors control the expression of the proneural genes in response to

extracellular molecules that assign spatial identity. Although it will be interesting to determine the role of these genes in CNS patterning, the embryonic profile of expression of some of them suggests that distinct molecular pathways may be used in adult PNS and embryonic CNS patterning.

1.10.3.2. Temporal Cues Control Neuroblast Differentiation

CNS development requires precise spatial as well as temporal cues. Indeed, fly neural precursors divide a fixed number of times and produce cells of distinct type at each division. For example, the first division of the 1-1 lineage always produces a GMC that gives rise to the aCC motorneuron and the pCC interneuron (in thorax and abdomen), whereas later divisions produce other types of motorneurons and interneurons in the thorax, and other types of interneurons as well as glia in the abdomen (Udolph *et al.*, 1993; Prokop and Technau, 1994). Thus, a temporal genetic program controls neural precursor differentiation.

Cell lineage, ablation, transplantation, *in vitro* culture, and genetic studies in *Drosophila* and others insects indicate that GMC birth order is the primary determinant of temporal identity (Doe and Goodman, 1985a, 1985b; Furst and Mahowald, 1985; Prokop and Technau, 1994; Weigmann and Lehner, 1995; Schmidt *et al.*, 1999). Recent studies have indeed shown that *Drosophila* NBs undergo temporally ordered changes in gene expression (review: Zhong, 2003). This suggests that, as NBs divide, they become temporally restricted in the type of cells that they can generate.

Good candidates to regulate this process are the transcription factors encoded by the *hunchback* (*hb*), *Krüppel* (*Kr*), *POU domain protein* (*pdm*), *castor* (*cas*), and *grainyhead* (*grh*) genes (Brody and Odenwald, 2000, 2002) (**Figure 12**). The *hunchback* and *Krüppel* genes are expressed in early-born neurons, *pdm* is expressed in middle-born neurons, while *castor* and *grainyhead* are expressed in late-born neurons. The *hb, Kr, pdm, cas* and *grh* genes are sequentially expressed in NBs, with the GMC/progeny maintaining this transcription factor profile at their birth.

This creates a layered structure, with each layer differing from the adjacent one by the expression of a specific transcription factor (**Figure 12a**). Expression of *hb* and *Kr* is necessary and sufficient to induce an early-born cell fate in multiple lineages (**Figure 12c**) (Isshiki *et al.*, 2001). Thus, *hb* and *Kr*

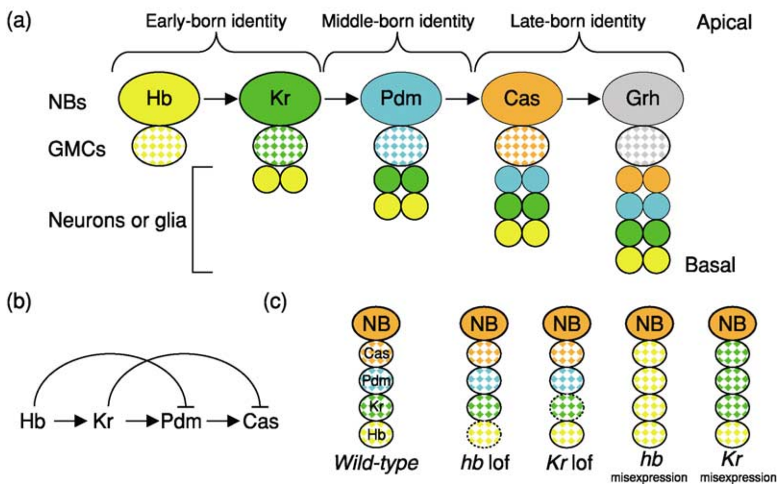

Figure 12 Temporal identity in NB lineages. (a) Schematic representation of a NB lineage: the neuroblast (NB), the ganglion mother cell (GMC), and its neuronal/glial progeny are represented from apical to basal. Color coding indicates specific gene expression and subdivides the lineage into adjacent layers according to birth date. During each temporal window of gene expression, GMCs are marked by the continuous presence of the temporal factor that is expressed in the NB at its birth. These transcription factors are also detected in postmitotic cells (neurons or glia). (b) Cross-regulation amongst ''temporal'' transcription factors. Loss-of-function and gain-of-function studies indicate cross-regulatory interactions between ''temporal'' transcription factors. Arrows and T-bars indicate activation and repression, respectively. These interactions ensure the sequential progression of temporal states during lineage development. (c) Schematic representation showing the temporal sequence of gene expression in wild-type and mutant GMCs. In wild-type, ''temporal'' genes are expressed in the NBs (large ovals) as well as in their progeny, the GMCs (lozenge-patterned small ovals). In loss-of-function (lof) *Hb* or *Kr* mutant embryos, the first or the second born identities are lost in the NB progeny, respectively. Conversely, forced continuous expression of Hb or Kr leads to the transformation of late-born identity to first or second born identity in the GMCs, respectively. Dashed circles represent abnormal GMC development (GMC transformed to a later born identity or dying GMC).

specify "early" temporal identity in *Drosophila* neural precursors.

These data indicate that loss of a temporal factor results in the alteration of neural identity in the layer in which this factor is usually expressed, and may lead to supernumerary cells expressing the transcription factor of the adjacent layer. These transcription factors, therefore, regulate the temporal identity (early versus late) of the NB and its progeny rather than cell fate (neuronal versus glial).

The molecular mechanisms underlying this temporal regulation are based on the fact that the transcription factor expressed in state 1 activates transcription factor in state 2 and represses transcription factor in state 3 (**Figure 12b**). For example, overexpression of Hb activates Kr and represses Pdm and Cas, whereas overexpression of Kr activates Pdm and represses Cas but has no effect on Hb expression leading to the model that each gene can activate the next gene in the pathway and repress the "next +1" gene (Brody and Odenwald, 2000; Isshiki *et al.*, 2001) (**Figure 12b**). Thus, temporal factors are responsible for upregulation of the next state, but also insulate the genetic program of adjacent temporal windows.

1.10.3.3. Molecular Control of Neuroblast Apoptosis, Quiescence, and "Reactivation"

The finding that temporal cues specify the identity of NB progeny raises an important question concerning the proliferative potential of neural stem cells. Fly NBs are submitted to a sharp proliferative control throughout development. Indeed, the number of cell divisions in the embryonic CNS depends on the type of NB. In most cases, the number of the progeny depends on the time of delamination, early-born NBs producing more neurons than late-born NBs (Bossing *et al.*, 1996, Schmidt *et al.*, 1997, 1999).

Moreover, the fly adult nervous system develops through extensive reorganization of the embryonic nervous system (review: Truman *et al.*, 1993) (see **Chapters 2.4** and **2.5**). A crucial pathway controlling this process is cell death by apoptosis in the sense that, once the embryonic nervous system has differentiated, some NBs undergo programmed cell death (Truman *et al.*, 1992) (see **Chapter 2.5**). For example, although each embryonic hemineuromere contains 30 NBs, their number decreases at later developmental stages. In the thorax of the larva, each neuromere retains about 23 NBs, while in the abdomen only three remain (Truman and Bate, 1988). Cell death genes of the *reaper* family account for this proapoptotic activity (Peterson *et al.*, 2002) (see **Chapter 2.5**).

Together with cell death, cell proliferation constitutes the other important pathway that determines the number of progeny and thereby shapes the adult CNS (Truman and Bate, 1988). While some NBs die, others stay quiescent and later resume proliferation ("NB reactivation") to build up the adult nervous system. The NBs that are reactivated at larval stages cease to proliferate completely after a specific number of divisions, and eventually die by apoptosis. The homeotic gene *abd-A* determines the final number of progeny that each precursor generates in the larval VNC (Bello *et al.*, 2003). Indeed, thoracic and abdominal NBs show extensive differences in the extent of proliferation. Larval thoracic NBs resume division earlier and divide for longer periods of time than abdominal NBs. A burst of expression of *abd-A* regulates the time at which cell death occurs in the larval life and, therefore, schedules the end of neural proliferation (Bello *et al.*, 2003). This shows that homeotic genes link positional information to neural proliferation. The cell-autonomous requirement of Abd-A implies that an intracellular signaling cascade controls this process. It would be interesting to determine whether the "temporal" factors play a role in controlling such death programs.

Recent studies have also shed some light on a molecular mechanism controlling neural stem cell proliferation in the brain. The Even-skipped (Eve) homeodomain containing transcription repressor acts nonautonomously to stimulate cell division of quiescent optic lobe NBs (Park *et al.*, 2001). Genetic studies have shown that Eve interacts with Terribly reduced optic lobes (Troll) and, indeed, mutations in this gene arrest NB proliferation (Voigt *et al.*, 2002). The vertebrate ortholog of *troll* encodes an extracellular matrix molecule that acts as a coreceptor for fibroblast growth factor 2 (FGF2) signaling, calling for a role of cell–cell interactions in the control of neural stem cell proliferation. Interestingly, mutations in these genes do not affect the proliferation potential of NBs that give rise to the embryonic CNS and are not programmed to die.

Building up the nervous system relies on the sequential activation of specific molecular and cellular pathways. While the maternal contribution defines the neurogenic territory, zygotic neuralizing factors and patterning genes allow the differentiation of distinct neural precursors at the right place and time. In addition, most genes work in a combinatorial fashion. The superimposition of homeotic, columnar, and segment polarity gene expression creates, within each neuromere, a Cartesian coordinate system, in which each precursor displays a unique combination of gene activity. Finally, each step must integrate with the

others, as shown by the observation that patterning genes activate proneural genes and that temporal factors control each other's activity. This intricate network of pathways guarantees the fine-tuning that is necessary for the establishment of a very complex array of neural precursors.

1.10.4. Neuroblasts and Asymmetric Divisions

1.10.4.1. Neuroblast Lineages and Asymmetric Divisions

Positional and proneural cues induce NB patterning and formation, respectively, and endow cells with specific identities in the absence of cell division. NB delamination triggers a second phase of cell specification, in which cells of the nervous system acquire distinct identities upon divisions that are asymmetric.

Asymmetric cell divisions play a crucial role in the establishment of cell diversity during development (Matsuzaki, 2000; Doe and Bowerman, 2001; Knoblich, 2001; Segal and Bloom, 2001). Asymmetry may be directed by extrinsic cues via cell–cell interaction between the progeny of a precursor cell. Alternatively, it may originate through the unequal segregation of intracellular determinants that direct distinct identities in each of the daughter cells. Although these represent extreme situations, in many instances both processes are required in the same division.

Asymmetric divisions of NBs and GMCs play crucial roles in specifying neural cell types and neuronal/glial identities, respectively (review: Fuerstenberg *et al.*, 1998). NB division is asymmetric in both size and identity of daughter cells (review: Doe *et al.*, 1998). Typically, NBs divide perpendicularly to the neuroepithelial layer and produce a GMC, from the basal side of the parent NB. While NBs undergo this type of asymmetric division repeatedly, GMCs divide only once along the same axis as the NB and produce two distinct cells that do not divide any more (review: Fuerstenberg *et al.*, 1998). NB and GMC divisions are characterized by stereotyped localization of fate determinants.

1.10.4.2. Role of Prospero/Numb in the Induction of the GMC Fate

The asymmetric divisions in *Drosophila* neural precursors have begun to be elucidated by the discovery of the asymmetric segregation of two key proteins, Prospero (Pros) and Numb, which are synthesized in NBs and asymmetrically segregate to the GMC (Doe *et al.*, 1991; Rhyu *et al.*, 1994; Knoblich *et al.*, 1995).

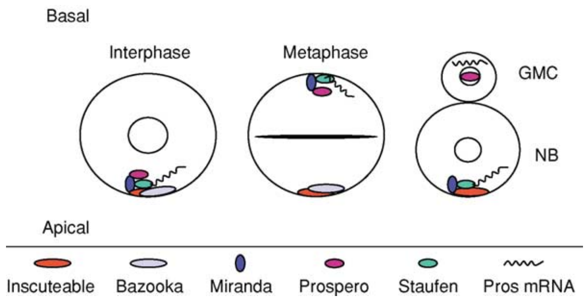

Figure 13 Distribution of cell fate determinants during the NB mitotic cycle. At late interphase, Miranda, Prospero (protein and mRNA), and Staufen are concentrated at the apical cortex and colocalize with Inscuteable and Bazooka. At metaphase, Miranda, Prospero (protein/mRNA), and Staufen move to the basal cortex whereas Inscuteable and Bazooka remain at the apical cortex. During telophase, most members of the basal complex are incorporated into the newly forming GMC. Then, Prospero translocates into the nucleus to activate GMC specific genes. Prospero and all the members of the basal complex (except Bazooka) are synthesized *de novo* in the precursor as the new mitotic cycle begins.

The *prospero* (*pros*) gene encodes a transcription factor that is expressed in all embryonic and larval NBs (Vaessin *et al.*, 1991). It is localized at the NB cortex in a highly cell cycle-dependent fashion (Hirata *et al.*, 1995; Knoblich *et al.*, 1995; Spana and Doe, 1995). At late interphase, Pros resides at the apical NB cortex in a diffuse crescent (**Figure 13**). As the NB enters mitosis, Pros is transported to the opposite side where it forms a tight crescent centered over the basal centrosome (**Figure 13**). As the GMC buds from the NB during anaphase, Pros is tightly associated with the basal cell cortex and ultimately segregates into the GMC, where it translocates into the nucleus (**Figure 13**). Nuclear Pros activates GMC-specific gene expression and represses NB-specific gene expression (Doe *et al.*, 1991; Hirata *et al.*, 1995; Knoblich *et al.*, 1995) (**Figure 13**). The complex regulation of subcellular Pros localization in the NB has two consequences: on one hand, it makes it possible to create progeny with distinct identity from a multipotent precursor and, on the other hand, it keeps the fate determinant inactive in this precursor.

It has been shown that *pros* mRNA is also asymmetrically localized in the NB in a cell cycle-dependent manner, and segregates to the GMC following mitosis (Li *et al.*, 1997; Broadus *et al.*, 1998) (**Figure 13**). In embryos lacking the RNA binding protein Staufen (Stau), the majority of NBs fail to localize *pros* mRNA (but not protein) apically at interphase or basally at mitosis, indicating that Stau controls *pros* mRNA localization independently of the Pros protein (Li *et al.*, 1997; Broadus *et al.*,

1998). In *staufen* (*stau*) mutants, the GMC fate is not affected, indicating that segregation of *pros* RNA is not sufficient to trigger GMC identity (Broadus *et al.*, 1998). However, loss of localization of *pros* mRNA or Stau alters GMC development in embryos that contain reduced levels of Pros protein, suggesting that *pros* mRNA and protein localization act redundantly to specify the GMC identity (Broadus *et al.*, 1998). This double control at the *pros* mRNA and protein levels reflects the requirement for fine-tuning in the building up the nervous system.

The *numb* gene encodes a membrane-associated protein (Uemura *et al.*, 1989) that shows the same cell cycle-dependent basal localization as seen for Pros (Rhyu *et al.*, 1994). Numb localizes normally in *pros* mutants, and Pros segregates normally in *numb* mutant embryos, indicating that the two proteins are independently localized (Knoblich *et al.*, 1995; Spana and Doe, 1995). Asymmetric localization of Numb initially requires the Partner of Numb (Pon) protein, which directly binds and colocalizes with Numb in dividing neural precursor cells (Lu *et al.*, 1998). However, Numb appears to be still attached to the cell cortex in the absence of Pon, indicating that other components likely play a role in Numb localization (Lu *et al.*, 1998). It has been recently shown that *jumeaux* (*jumu*), a winged-helix transcription factor encoding gene, is necessary to correctly localize and segregate the Pon–Numb complex (Cheah *et al.*, 2000), suggesting that unknown target genes activated by Jumeaux play a crucial role in this process.

It is unclear why Numb needs to be asymmetrically distributed during NB division, since there is no reported function of *numb* in the GMC. Nevertheless, Numb does play an important role in the specification of sibling cell identity (reviews: Buescher *et al.*, 1998; Cayouette and Raff, 2002). In most cases, the two daughter cells, A and B, produced after each GMC division are distinct. It has been shown that Numb antagonizes Notch signaling, probably by direct interaction with the Notch intracellular domain (NICD) (Spana and Doe, 1995; Guo *et al.*, 1996). *Notch* loss-of-function mutations lead to the production of two similar daughter cells (A/A) whereas *numb* mutations lead to a reciprocal phenotype (B/B) (Buescher *et al.*, 1998; Lear *et al.*, 1999). Thus, asymmetric segregation of Numb biases Notch signaling between daughter cells to create distinct cell identities. This underlines the role of both autonomous and nonautonomous pathways in the establishment of cell diversity and the importance of crosstalk between these molecular pathways in asymmetric divisions.

1.10.4.3. Genes Involved in Asymmetric Cell Division

The establishment of different identities via asymmetric division requires the integration of two processes: segregation of cell fate determinants and correct orientation of the mitotic spindle, i.e., orientation parallel to the polar distribution of these determinants.

Inscuteable protein (Insc) is necessary for the coordination of orientation of the mitotic spindle with protein localization (Kraut and Campos-Ortega, 1996; Kraut *et al.*, 1996; Tio *et al.*, 1999). Insc is localized at the apical cortex of the NB and is first detected in the apical endfoot that remains associated with the epithelial surface in the delaminating NB (**Figure 13**). The apical crescent of Insc persists in the NB through metaphase. After metaphase, it appears to be delocalized or degraded (Kraut *et al.*, 1996) (**Figure 13**). In *inscuteable* (*insc*) mutant embryos, the orientation of the mitotic spindle is random with respect to the apicobasal axis (Kraut and Campos-Ortega, 1996). Moreover, Pros and Numb are either homogeneously localized at the cortex or localized in crescents whose positions are randomized with respect to the surrounding tissue during mitosis (Kraut *et al.*, 1996). Insc appears to independently regulate both spindle orientation and basal localization of Pros and Numb during mitosis. Once Insc localization is established in the NB, all known molecular and cellular asymmetries assayed to date are positioned with respect to Insc.

1.10.4.3.1. How is Insc localization regulated? Previous work has identified Bazooka (Baz), a PSO95/DLG/ZO-1 (PDZ) domain containing protein that binds Insc (Kraut and Campos-Ortega, 1996; Ikeshima-Kataoka *et al.*, 1997; Shen *et al.*, 1997; Kuchinke *et al.*, 1998) (**Figure 13**). Removal of both maternal and zygotic Bazooka products results in the uniform distribution of Insc in the NB cytoplasm and causes defects in the distribution of cell fate determinants and in spindle orientation similar to those seen in *Insc* mutant embryos (Schober *et al.*, 1999; Wodarz *et al.*, 1999). Indeed, when NBs delaminate from the epithelium, Bazooka colocalizes with Inscuteable and recruits it to the apical cortex in NBs.

The *bazooka* (*baz*) gene has been shown to be required for the polarity of epithelial cells, in which its protein is localized at the apical cortex (Muller and Wieschaus, 1996). This supports the idea that NBs inherit the apicobasal polarity from the epithelium. Two proteins, Par-6 and atypical protein kinase C (aPKC), colocalize with Bazooka

and form a complex at the apical cortex of NBs. The *par-6* gene encodes a PDZ containing protein (Petronczki and Knoblich, 2001) and *aPKC* encodes a serine/threonine kinase (Wodarz *et al*., 2000). In *par-6* or *aPKC* mutant embryos, defects are seen in the apical localization of Bazooka and Insc in NBs, as well as in the orientation of the spindle (Wodarz *et al*., 2000; Petronczki and Knoblich, 2001). These results indicate that a functional complex between Bazooka, Par-6, and aPKC plays a role in polarizing NBs to localize Inscuteable properly following delamination.

Strikingly, *insc* mutations show a relatively low penetrant phenotype (Kraut and Campos-Ortega, 1996; Kraut *et al*., 1996). Since no Insc homologs exist in flies, it is likely that additional proteins are necessary to coordinate mitotic spindle organization and fate determinant localization. Using cell specific markers, it will be interesting to determine whether Insc affects specific NBs or whether it affects all NBs but is only required in some divisions within the neuroblast lineage (early versus late, for example).

Recently, it has been shown that asymmetrical localization of Insc requires the presence of Partner of Inscuteable (Pins), a protein with multiple repeats of the tetratricopeptide motif as well as motifs implicated in binding of Gα proteins (Schaefer *et al*., 2000; Yu *et al*., 2000). Pins colocalizes with Insc at the apical cell cortex in interphase and mitotic neuroblasts, and loss of Pins results in the same phenotype as seen in *insc* mutant embryos (Bellaiche *et al*., 2001). Moreover, the G protein α subunit Gαi binds and localizes Pins at the cortex, and the effects of loss of Gαi or Pins are very similar, supporting the idea that Pins/Gαi act together to mediate neuroblast asymmetric division (Schaefer *et al*., 2000). In general, the three subunits that compose the G protein (α, β, and γ) localize together at the proximity of seven transmembrane domain receptors also known as G protein-coupled receptors (GPCRs). Signal transduction signaling involves GPCR activation and dissociation of the three subunits, which triggers an intracellular molecular cascade (Offermanns, 2003) (see **Chapter 5.5**). Interestingly, binding of Pins to Gαi can cause the release of the Gβ subunit from Gαi, suggesting that Gαi may function during asymmetric cell division via a receptor-independent mechanism (review: Knust, 2001). This suggests that an intracellular process may regulate G protein activation.

These data demonstrate that Pins and Insc are dependent on each other for asymmetric localization, and suggest that a receptor-independent G protein signaling is required to mediate and coordinate basal protein localization with mitotic spindle orientation (reviews: Schaefer *et al*., 2000; Knust, 2001; Schaefer *et al*., 2001).

1.10.4.3.2. How is Pros localization regulated? Starting from the identification of Pros partners, it has been possible to dissect the molecular cascade triggering cell diversity in the nervous system. Miranda (Mira), a coiled-coil protein, was identified in a two-hybrid screen using the asymmetric localization domain of Pros (Ikeshima-Kataoka *et al*., 1997; Shen *et al*., 1997). *Miranda* mutations result in a failure to correctly localize Pros during or after NB division resulting in its nuclear localization in both NB and GMC (Ikeshima-Kataoka *et al*., 1997). The search for mutations that alter Mira localization in metaphase NBs lead to the identification of *lethal giant larvae* (*lgl*), *disc large* (*dlg*), and *scribble* (*sbb*), three tumor-suppressor encoding genes (Albertson and Doe, 2003). In embryos mutant for any of these genes, Mira is mislocalized (Albertson and Doe, 2003). Surprisingly, Insc localization and spindle orientation are correct, indicating that these proteins act specifically to polarize Mira by a pathway that does not involve Insc (Albertson and Doe, 2003). Therefore, although Mira is required for Pros localization to the cortex, it has no role in the establishment of an asymmetric division (**Figure 13**).

In conclusion, the asymmetric division of NBs requires multiple pathways that regulate independently the different aspects of subcellular localization of cell fate determinants.

1.10.5. Glial Differentiation in the Fly CNS

Embryonic *Drosophila* glial cells can be classified into three major categories depending on position, morphology and gene expression: surface-associated, cortex-associated, and neuropil-associated glia (Ito *et al*., 1995; Hartenstein *et al*., 1998). Nevertheless, considering the origin and molecular details of the developmental program, CNS glial cells can be subdivided into two populations: lateral glia (LG) and midline glia (MG) (reviews: Giangrande, 1996; Granderath and Klambt, 1999; Jacobs, 2000; Van De Bor and Giangrande, 2002). LG originate from the neuroectoderm and are located throughout the CNS, whereas MG originate from the mesectoderm and are located at the midline. Some 60 LG and six MG are present in each neuromere. All LG differentiation is under the control of *glial cell deficient/glial cell missing* (*glide/gcm*) locus (review: Van De Bor and Giangrande, 2002), whereas MG differentiation requires *single-minded* (*sim*) (Crews

et al., 1992). In the absence of LG, MG development is normal and vice versa, showing that these two developmental programs are completely independent.

1.10.5.1. Midline Glia Differentiation

As seen before, MG determination is under the control of the Sim/Tgo heterodimer, which likely activates the expression of DER (Jacobs, 2000). DER is specifically expressed and required in MG cells, as shown by the finding that DER hypomorph embryos lack all MG at the end of embryogenesis (Zak *et al.*, 1990; Scholz *et al.*, 1997; Stemerdink and Jacobs, 1997). The main activating ligand for DER at the midline is Spitz (Spi) (Schweitzer *et al.*, 1995b), a fly ortholog of vertebrate transforming growth factor-α (TGF-α) (Rutledge *et al.*, 1992). Moreover, Rhomboid (Rho; a seven transmembrane protein) and Star (a transmembrane protein) are primary regulators of Spitz signaling (Sturtevant *et al.*, 1993; Guichard *et al.*, 1999). Indeed loss-of-function of *spitz, rho*, or *star* results in a decrease in MG number (Sonnenfeld and Jacobs, 1994; Lanoue and Jacobs, 1999; Pickup and Banerjee, 1999). Rho and Star are both expressed throughout the mesectoderm before being restricted to MG. Star is required for the relocalization of Spi from the endoplasmic reticulum to the Golgi apparatus (**Figure 14**). There, Rho cleaves Spi in its intramembrane domain, producing a soluble form of Spi that is secreted and activates DER (Lee *et al.*, 2001; Urban *et al.*, 2001). Ligand binding to DER activates the Ras pathway leading to phosphorylation and thereby activation of the transcription factor Pointed P2 (PntP2) (Jacobs, 2000). In the absence of *pntP2*, embryos display a fused commissures phenotype, which is characteristic of MG differentiation defects (see below) (Klambt, 1993). This indicates that PntP2 is required for MG development.

During embryonic development, some of the MG undergo programmed cell death (Sonnenfeld and Jacobs, 1995; **Chapter 2.5**). This process is controlled by *argos*, a direct target of PntP2 that is expressed in a subpopulation of MG (Scholz *et al.*, 1997). The *argos* gene encodes a secreted protein acting as an antagonist of DER signaling by interfering with Spi-mediated dimerization of DER (Schweitzer *et al.*, 1995a; Jin *et al.*, 2000). Ubiquitous expression of *argos* results in the shutdown of DER expression (Schweitzer *et al.*, 1995a), suggesting that *argos*-expressing cells repress expression of DER in other MG, which eventually die. However, the way in which cells that secrete Argos are protected from an autocrine repression of DER

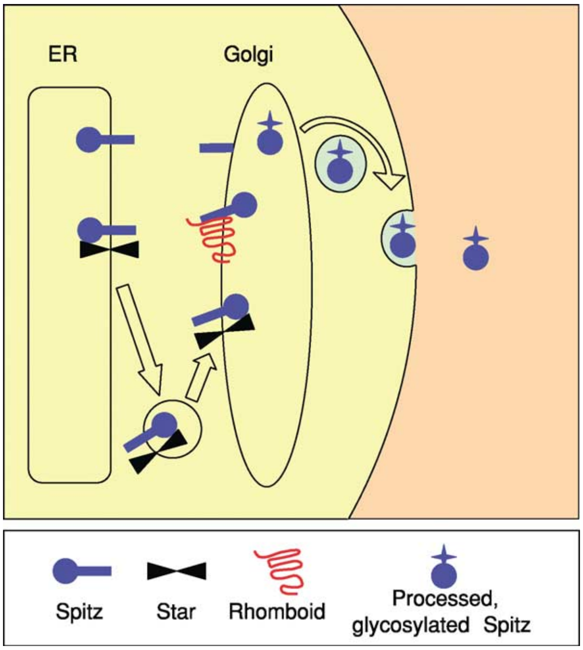

Figure 14 Mechanism of Spitz processing. Spitz (blue) is retained in the endoplasmic reticulum (ER) until Star (black) promotes its relocalization into the Golgi apparatus. There, Rhomboid (red) cleaves the Spitz protein, which is subsequently glycosylated (blue circle with spine) and secreted. (Modified from Lee, J.R., Urban, S., Garvey, C.F., Freeman, M. **2001**. Regulated intracellular ligand transport and proteolysis control egf signal activation in *Drosophila*. *Cell 107*, 161–171.)

signaling is poorly understood. The existence of a programmed cell death pathway in the midline population clearly indicates that the acquisition of the proper number of MG involves and requires the balance between two developmental pathways, cell differentiation and death.

1.10.5.2. Lateral Glia Differentiation

1.10.5.2.1. The *glide/gcm* glial promoting factor As described above, LG arise from pure (glioblasts) and mixed precursors (neuroglioblasts), all expressing and depending for function on a single locus, irrespective of precursor type (review: Van De Bor and Giangrande, 2002). This locus contains the *glide/gcm* and *glide2* genes, which encode related transcription factors of a novel type (Hosoya *et al.*, 1995; Jones *et al.*, 1995; Vincent *et al.*, 1996; Kammerer and Giangrande, 2001; Alfonso and Jones, 2002) (**Figure 15a**). The *gcm* DNA-binding motif is conserved throughout evolution and provides a signature for the *gcm* gene family (Akiyama *et al.*, 1996; Schreiber *et al.*, 1997; Miller *et al.*, 1998; Kammerer and Giangrande, 2001). In embryos lacking *glide/gcm*, most LG are absent (Hosoya *et al.*, 1995; Jones *et al.*, 1995; Vincent *et al.*, 1996). Moreover, ectopic expression of *glide/gcm* is sufficient to

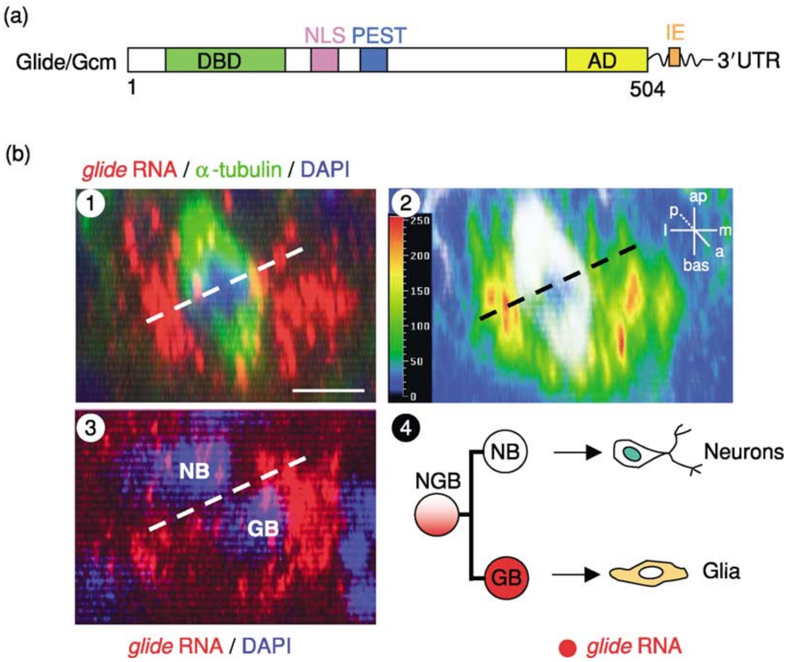

Figure 15 The role of *glide/gcm-glide2* in the determination of the glial fate. (a) Predicted Glide/Gcm mRNA structure with the encoded protein domains shown in blocks. DBD, DNA-binding domain; NLS, nuclear localization signal; PEST, rapid turnover signature; AD, activation domain; IE, instability element; UTR, untranslated region. (b) The NGB 6-4T lineage: α-tubulin labels the mitotic spindle 4′-6-diamidino-2-phenylindole (DAPI) the chromatin. (1, 2) Early NGB 6-4T anaphase: *glide* RNA is asymmetrically localized at the basoanterior pole of the cell. Dotted line is located in the middle of chromatin labeling. Scale bar = 4 μm. In (2), α-tubulin labeling (white) is superimposed to the quantification data relative to *glide* RNA. Color coding at left represents different levels of RNA accumulation: the lowest (0) is represented in blue, the highest (250) in red. ap, apical; bas, basal; a, anterior; p, posterior; l, lateral; m, medial. (3) The NGB 6-4T daughter cells, NB and GB, soon after division. Note that *glide* RNA is preferentially inherited by the GB. NB, neuroblast; GB, glioblast. (4) Schematic of *glide* mode of action during NGB 6-4T division. NGB, neuroglioblast. (Modified from Van De Bor, V., Giangrande, A. **2002**. *glide/gcm*: at the crossroads between neurons and glia. *Curr. Opin. Genet. Devel. 12*, 465–472.)

promote the glial fate within and outside the nervous system (Jones *et al*., 1995; Vincent *et al*., 1996; Akiyama-Oda *et al*., 1998; Bernardoni *et al*., 1998). Expression of *glide2* is also sufficient to promote the glial fate, but its absence has no effect on glia determination, suggesting that it plays a minor role during gliogenesis (Kammerer and Giangrande, 2001; Alfonso and Jones, 2002). In the absence of Glide/Gcm-Glide2, glial cells are absent because they are all transformed into neurons. This suggests that the *glide/gcm* locus activates the glial program and represses the neuronal one (Hosoya *et al*., 1995; Jones *et al*., 1995; Vincent *et al*., 1996; Giesen *et al*., 1997; Bernardoni *et al*., 1998, 1999; Miller *et al*., 1999; Van De Bor *et al*., 2000; Kammerer and Giangrande, 2001). Thus, these genes trigger the glial cell fate by controlling the fate choice between glia and neurons in multipotent precursors (reviews: Wegner and Riethmacher, 2001; Van De Bor and Giangrande, 2002) (**Figure 15b**).

The role of *glide/gcm* has been extensively investigated in two lineages, the 6-4T and the 6-4A, examples of type 1 NGB and pure GB, respectively (Akiyama-Oda *et al*., 1999; Bernardoni *et al*., 1999; Ragone *et al*., 2001). During division of the 6-4A, *glide/gcm* mRNA is equally distributed in the two daughter cells leading them towards a glial fate. In multipotent precursors, the fate choice relies on a *glide/gcm* posttranscriptional control. The *glide/gcm* RNA forms a cytoplasmic gradient in the NGB, which leads to one daughter cell inheriting more *glide/gcm* transcripts than the other one (**Figures 7 and 15**). This cell (the GB) produces glia, whereas the other (the NB) produces neurons. Overexpression of *glide/gcm* in both 6-4T progeny cells results in expression of glial markers in both of them. The observation that daughters inheriting different amounts of the same cell fate determinant end up adopting distinct fates demonstrates the role of quantitative regulation in the establishment of cell diversity upon asymmetric division. This is further confirmed by the fact that *glide/gcm* is able to positively autoregulate its own expression (Miller *et al*., 1998). Although the NGB provides another example of asymmetric

division, the behavior of *glide/gcm* transcripts suggests that novel molecular mechanisms are necessary for the induction of the glial fate.

1.10.5.2.2. The *glide/gcm* targets execute the glial differentiation program Once *glide/gcm* has been activated, the glial differentiation program takes place. Because *glide/gcm* expression is transient, terminal glial differentiation is likely under the control of genes acting downstream of it. Some targets, such as *reverse polarity* (*repo*), *pointed P1* (*pntP1*), and *locomotion defects* (*loco-c1*), have been shown to execute the glial differentiation program, whereas others, e.g., *tramtrack69* (*ttk69*), inhibit the neuronal pathway. Other identified target genes are likely involved in the late differentiation steps of specific glial subtypes (Egger *et al.*, 2002; Freeman *et al.*, 2003).

The first identified target of *glide/gcm* is *reverse polarity* (*repo*), which encodes a paired-like homeodomain transcription factor expressed in all LG but not in MG (Campbell *et al.*, 1994; Xiong *et al.*, 1994; Halter *et al.*, 1995). Its promoter contains 11 Glide/Gcm consensus binding sequences, and Glide/Gcm is necessary and sufficient to induce *repo* expression *in vivo*, suggesting that *repo* represents a direct target of Glide/Gcm (Hosoya *et al.*, 1995; Jones *et al.*, 1995; Akiyama *et al.*, 1996; Vincent *et al.*, 1996; Bernardoni *et al.*, 1998). In *repo* mutant embryos, early gliogenesis occurs normally but late glial markers are not expressed, suggesting that Repo is required for terminal glia differentiation (Campbell *et al.*, 1994; Xiong *et al.*, 1994; Halter *et al.*, 1995; Yuasa *et al.*, 2003).

The *pointed* gene encodes two transcription factor isoforms containing an ETS DNA binding domain (Klambt, 1993; Klaes *et al.*, 1994). The ETS domain is a DNA binding domain found in a family of proteins to the vertebrate *ets* oncogene. While Pointed P2 (PntP2) is only present in MG (see above), Pointed P1 (PntP1) is specifically expressed in longitudinal glia (Klambt, 1993). In the absence of PntP1, longitudinal glia fail to develop normally leading to defects in connective formation (Klaes *et al.*, 1994). Thus, PntP1 is involved in terminal differentiation of longitudinal glia (Klaes *et al.*, 1994; Granderath *et al.*, 2000).

Interestingly, ectopic expression of either Repo or PntP1 leads to the activation of some glial-specific markers in few cells, whereas combined ectopic expression has a synergistic effect (Yuasa *et al.*, 2003). Repo and PntP1 do not affect each other's expression, and this suggests that their genes are independent targets of Glide/Gcm that participate in glial specification, i.e., the differentiation of a specific type of glial cell (Yuasa *et al.*, 2003).

As mentioned above, gliogenesis needs both activation of glial-specific genes and repression of neuronal-genes. The *tramtrack* (*ttk*) gene encodes a transcription factor of the zinc finger family (Harrison and Travers, 1990). One of the two Ttk isoforms, Ttk69, constitutes the only protein expressed in all glial cells (LG and MG) and participates in neural repression (Giesen *et al.*, 1997; Badenhorst, 2001). Ectopic expression experiments and analysis of its expression profile suggest that Ttk69 acts by repressing the neuronal fate rather than the early steps of neurogenesis (Badenhorst *et al.*, 1996). This is also confirmed by the observation that Ttk69 does not repress the expression of proneural genes (Badenhorst, 2001). In this process, Ttk69 seems to cooperate with Repo, although the molecular nature of this interaction is not yet understood (Yuasa *et al.*, 2003). Ttk69 also plays a role in glial proliferation, as *ttk* loss-of-function mutants display an increase in LG number, while gain-of-function mutants show the opposite phenotype (Badenhorst, 2001).

Taken together, these results suggest that lateral gliogenesis is dependent on a single locus (*glide/gcm–glide2*), which triggers the different pathways executing glial cell differentiation. Glial specification depends on cell-specific factors that allocate distinct identities to the different glial lineages. Such factors act at early stages, by controlling the spatially and temporally regulated transcription of the *glide/gcm* locus, but are also activated at later stages by interacting with the *repo* and *pntP1* genes (Klaes *et al.*, 1994; Ragone *et al.*, 2003; Yuasa *et al.*, 2003). These factors likely include those that dictate positional cues in the neural precursors, since they are expressed throughout the neural lineage up to postmitotic cells.

Thus, *Drosophila* represents an ideal model for achieving an in-depth understanding of the molecular pathways controlling glia differentiation. Moreover, elucidating the *glide/gcm* mode of action during neuron–glia fate decision process will afford a better understanding of the mechanisms that control multipotent stem cell decisions during development.

1.10.6. Neuronal–Glial Cell Interactions Control the Development of the Nervous System

Neurons and glial cells constitute the major components of the nervous system. Although they play distinct roles, their continuous interactions are a gage of appropriate development and function of such a complex tissue. Neuron–glia interactions

play important instructive roles during cell differentiation, migration, and axonal navigation, as well as in the regulation of cell survival (review: Laming *et al.*, 2000; see also **Chapter 2.3**).

Most glia arise from precursors that also produce neurons, the control between the two fates depending on the cell-autonomous cue Glide/Gcm (see Section 1.10.5.2.2). Upstream of this choice, however, a nonautonomous pathway must be activated, at least in some precursors. In the CNS as well as in the PNS, the Notch signaling cascade controls the expression of *glide/gcm* and thereby the activation of the glial fate (Udolph *et al.*, 2001; Van De Bor and Giangrande, 2001; Umesono *et al.*, 2002). The requirement of this pathway, which is conserved throughout evolution (review: Artavanis-Tsakonas *et al.*, 1999), clearly shows that both intrinsic and extrinsic cues act on the same fate decision and participate the establishment of cell diversity.

After neuronal differentiation, polarized extensions grow toward specific targets through the use of distinct cellular and molecular cues. The fly midline represents a classical model for the study of neuron–glia interactions controlling axonal guidance (reviews: Tear, 1999; Kaprielian *et al.*, 2001). Bilaterally symmetric animals are able to transmit information between the left and right sides of their body in order to integrate sensory input and coordinate motor output. Thus, many neurons in the CNS project so-called commissural axons across the midline. Interestingly, these axons are never observed to recross the midline (**Chapter 2.3**). However, some neurons project axons that remain on the ipsilateral side of the CNS, without ever crossing the midline (reviews: Tear, 1999; Kaprielian *et al.*, 2001; **Chapter 2.3**). Many, if not most, of the fly navigational cues are provided by midline glia and their precursors (review: Lemke, 2001). Thus, Netrin (Net) chemoattractants, which are expressed in midline glia, attract axons, which express the Netrin receptor Frazzled (Fra) and allow them to cross the midline (review: Livesey, 1999). Disruption of the *netrin* (*net*) or *frazzled* (*fra*) gene leads to a reduction in the number of commissural axons tracts (Harris *et al.*, 1996; Kolodziej *et al.*, 1996; Mitchell *et al.*, 1996). However, neither mutation leads to a complete loss of all commissural axon connections (Kolodziej *et al.*, 1996; Hummel *et al.*, 1999a, 1999b), suggesting that other genes are also involved in this process. It was shown that two other mutations, *schizo* (*siz*) and *weniger* (*weg*), induce a reduced commissure phenotype (Hummel *et al.*, 1999a, 1999b). *Schizo* and *weg* mutant embryos show a more severe phenotype than that observed in *fra* embryos; however, commissural axons are still not affected. Genetic analyses indicate that the *net/fra* and *siz/weg* genes act in parallel pathways (Hummel *et al.*, 1999a, 1999b). Therefore, *siz* and *weg* encode new, yet undefined, components guiding commissural growth cones towards the midline (Hummel *et al.*, 1999a, 1999b). The molecular characterization of these genes will likely identify new molecules, which also play a role in axon guidance during vertebrate CNS development.

While Netrins are essential for at least some commissural axons to grow across the midline, the choice of a contralateral versus ipsilateral pathway is dictated by the extracellular matrix protein Slit (Sli), which is secreted by midline glial cells and found associated with the surface of axons (Rothberg *et al.*, 1988, 1990). Sli repels axons that express the Roundabout (Robo) proteins (Kidd *et al.*, 1999). Repulsion prevents ipsilaterally projecting axons from entering the midline and contralaterally projecting axons from re-entering the midline once they have crossed it (Kidd *et al.*, 1998c). Three *robo* genes, (*robo1, 2, 3*) have been identified in *Drosophila*, all encoding proteins belonging to the IG-CAM family (Seeger *et al.*, 1993; Kidd *et al.*, 1998c; Rajagopalan *et al.*, 2000; Simpson *et al.*, 2000). Loss of the three proteins mimics the commissure-collapsed phenotype observed in *slit* mutant embryos (Rajagopalan *et al.*, 2000). Axons extending toward or across the midline express very low levels of Robo proteins; in contrast, crossed segments of commissural axons as well as ipsilaterally projecting axons express high levels of Robo proteins (**Figure 16**). This suggests that Robo proteins normally prevent midline crossing and function as receptors for the Slit inhibitory ligand, which is localized at the midline (Brose *et al.*, 1999; Kidd *et al.*, 1999).

The transmembrane protein Commissureless (Comm) is normally required for axons to cross the midline, and behaves as a powerful negative regulator of Robo, as was evidenced by its mutant phenotype (Seeger *et al.*, 1993; Tear *et al.*, 1996; Kidd *et al.*, 1998c) (**Figure 16**). Tissue culture experiments have shown that coexpression of Comm and Robo alters Robo's subcellular localization (Kidd *et al.*, 1998b). In the absence of Comm, Robo protein accumulates at the cell surface; however, when both proteins are present, Robo colocalizes with Comm to intracellular compartments, which are probably late endosomes (**Figure 16**). Moreover, Comm needs to interact with Robo to affect Robo's localization (Keleman *et al.*, 2002). These findings suggest that Comm prevents Robo from reaching the cell surface by binding and targeting it directly to endosomes. One model proposes that this depends on Comm ubiquitination by the DNedd4 ubiquitin

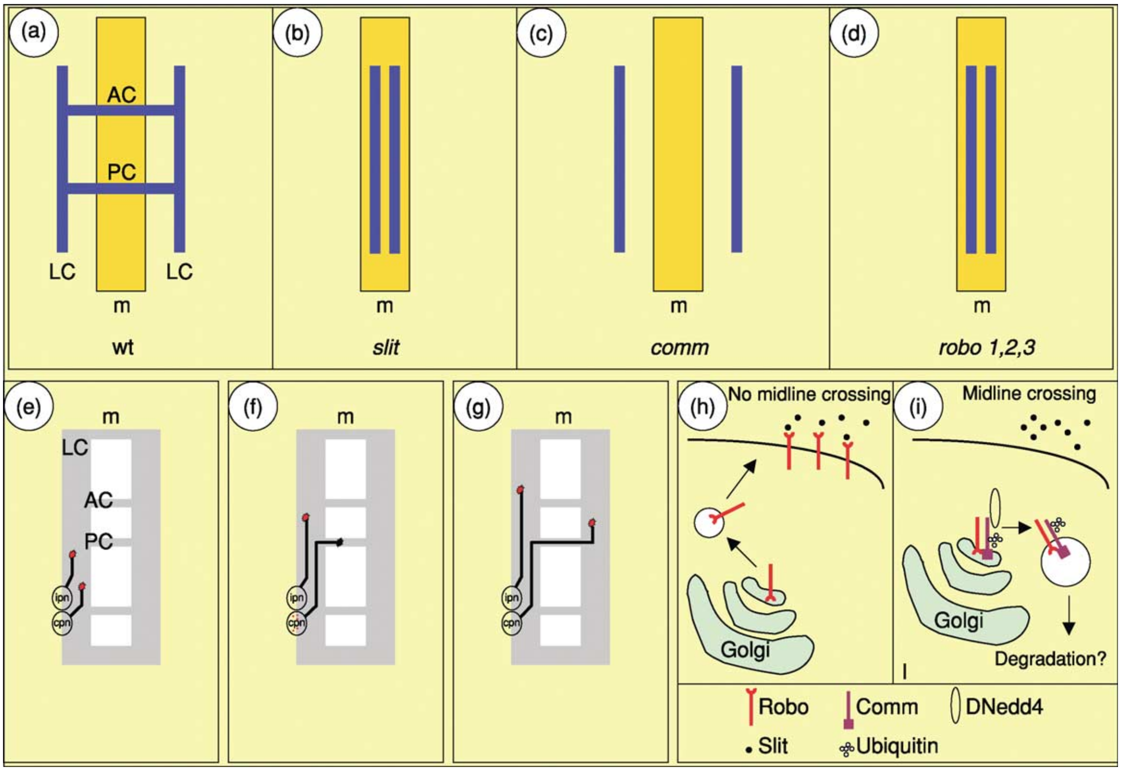

Figure 16 The role of the *slit–robo–comm* pathway in axon guidance at the fly midline. (a) In wild-type embryos, the ventral cord displays two longitudinal connectives (LC) running parallel on each side of the midline (m), an asymmetric structure that is crossed by the anterior and the posterior commissures (AC and PC, respectively). (b) In *slit* mutant embryos, all axons enter the midline but never leave it, resulting in a collapsed commissure phenotype. (c) An opposite phenotype is seen in *comm* mutant embryos in which axons never cross the midline. (d) Gene *robo1, 2, 3* triple mutant embryos show the same phenotype as that observed in *slit* embryos, i.e., collapsed commissures. (e) Initially, both growth cones of ipsilateral (ipn) and contralateral (cpn) axons express Robo (in red). (f) Comm is specifically expressed in the cpn while they are crossing the midline. This results in a loss of Robo at the cpn growth cone membrane. (g) Once cpn axons have crossed the midline, Comm expression is downregulated and Robo is present again at the cpn growth cone membrane. This allows repulsion by Slit, which prevents a new cross. The ipn axon never expresses Comm and never crosses the midline. (h) Neurons only expressing Robo (constitutively in ipn; before and after but not during midline crossing in cpn), accumulate it at the membrane. Axons can then respond to the Slit repellent signal and do not cross the midline. (i) Neurons expressing Comm and Robo do not accumulate Robo at the membrane and, as a consequence, are unable to respond to Slit and cross the midline. In these axons, Slit/Robo signaling is blocked by a mechanism involving ubiquitination of Comm by DNedd4. This ubiquitination step facilitates the sorting of Comm and Robo in late endosomes. Once the cpn has crossed the midline, Comm expression is downregulated and Robo is present again at the membrane.

ligase, which sequesters Robo away from the cell membrane, its site of action (Myat *et al*., 2002) (**Figure 16**). These studies clearly identify neuron–glia interactions as privileged cell–cell communication for the establishment of correct axonal trajectories. The fact that these cellular and molecular pathways are conserved throughout evolution (Keleman *et al*., 2002) emphasizes the importance of such interactions.

In the mature embryo, glial–neuronal interactions are pivotal for the homeostasis of the nervous system, and this is achieved through their influence on the control of glial and neuronal survival (Hidalgo *et al*., 2001; Bergmann *et al*., 2002). The importance of such interactions is highlighted by the finding that neurons send signals that control glial cell numbers, and glial cells send signals that control neuronal cell numbers. Two different members of the EGF family, Vein (Vn) and Spi, were shown to function as gliatrophins in *Drosophila*. Thus, it was demonstrated that the neuregulin homolog Vein maintains survival of a subpopulation of longitudinal glia (Hidalgo *et al*., 2001), while the TGF-α homolog Spi maintains survival of midline glia (Bergmann *et al*., 2002). In both cases, the trophic ligands are secreted by adjacent axons at concentrations that are sufficient for the survival of only a subset of the target glial population.

Conversely, mutations in genes specifically expressed in glia affect neuronal survival. The *repo* gene is expressed and required in all fly glial cells (Halter *et al*., 1995). In flies homozygous for a viable

allele of *repo*, neurodegeneration is observed in the eye, showing that alteration of glial cell function leads to neuronal death (Xiong and Montell, 1995). Similar results were described in other glia-affecting mutants like *drop-dead* (*drd*) or *swiss-cheese* (*sws*) (Buchanan and Benzer, 1993; Kretzschmar *et al.*, 1997). These two genes are expressed by glial cells and in mutant flies homozygous for each of these genes, glial cells differentiate abnormally leading to neuronal death. Finally, in *glide/gcm* embryos, where almost all glia are missing, neuronal apoptosis occurs during development (Hosoya *et al.*, 1995; Jones *et al.*, 1995; Vincent *et al.*, 1996).

Once neurons and glia have differentiated, they move to reach their final destination within the CNS and the PNS (review: Hatten, 1999) (see **Chapter 2.3**). Indeed, cell migration is a hallmark of nervous system development and is responsible for the generation of the layered structure of the vertebrate CNS (reviews: Tsai and Miller, 2002; Honda *et al.*, 2003). The migratory process entails several steps: cells have to initiate migration, find the direction of movement, and stop migrating as they reach the final destination. The complex and timed process of migration has been mostly analyzed in glial cells of the PNS, which displays a simpler organization than the CNS (Sepp *et al.*, 2000; Tsai and Miller, 2002; Sepp and Auld, 2003). These studies have demonstrated that, in some tissues, glial cells use axons as a migratory substratum (wing-associated glia) whereas in others they do not (eye-associated glia) (Giangrande *et al.*, 1993; Choi and Benzer, 1994; Giangrande, 1994; Rangarajan *et al.*, 1999; Van De Bor *et al.*, 2000). The different glial migratory behaviors observed so far underscore the diversity of developmental strategies used in time and space to make cells reach their final destination.

The study of a dynamic process such as migration has often been limited by two factors. On one hand, most commonly used techniques for labeling cell types rely on the fixation of samples (Ono *et al.*, 1997; Affolter and Shilo, 2000; Sugimoto *et al.*, 2001); on the other hand, real-time analyses have been realized in cell culture systems and/or sliced tissues, due to the nervous system complexity. The recent development of green fluorescent protein (GFP)-based tools has opened new perspectives for the analysis of dynamic processes in whole animals and in real time (review: Yu *et al.*, 2003). This non-invasive approach will certainly provide new and important information on the role of neuron–glia interactions in the control of glial cell migration.

Although neurons and glia have very distinct roles, these data clearly demonstrate that the continuous interaction between these two cell types plays a fundamental role in neural development, and that neurons or glial cells must be considered as a whole, in order to understand their differentiation and role.

1.10.7. Evolutionary Aspects of Insect CNS Development

Much of what was initially learned on embryonic nervous system development comes from studies on large insects. Indeed, neural precursors were first identified in grasshopper embryos (Wheeler, 1891), in which it is possible to predict the identity of individual neural precursor with 100% certainty solely on the basis of its stereotyped size, morphology, and position in the neurogenic region (Raper *et al.*, 1984; Taghert and Goodman, 1984; Doe and Goodman, 1985a). By comparison, the early and most of the late-forming neural precursors can be unequivocally identified in *Drosophila* by their morphology, while the use of molecular markers is necessary for the identification of the others (Doe, 1992).

Morphological analysis of neural precursor lineages shows that subtle differences exist between *Drosophila* and the grasshopper. In *Drosophila*, the ectodermal cells adjacent to the neural precursors extend processes around the precursor, which are withdrawn soon after the latter begin to divide. In the grasshopper, these cells differentiate into “sheath cells,” which maintain processes that wrap around the GMCs and the neurons/glial cells produced from a single neural precuror (Doe and Goodman, 1985a) (**Figure 17**). As a consequence, the progeny of individual *Drosophila* neural precursor are not “packaged” together in a line, instead GMCs and neurons from adjacent neural precursors intermingle in the CNS (Doe, 1992). In addition, the grasshopper has one cell type that is not present in *Drosophila*, the cap cell, which is attached to the ventral surface of every neural precursor and is required for its asymmetric divisions (Kawamura and Carlson, 1962) (**Figure 17**).

1.10.7.1. Neural Precursor Identity and Positional Cues

With respect to position and timing of formation, pattern of gene expression and cell lineage, the development of neural precursors in *Drosophila* is similar to that observed in the larger grasshopper embryo (Bate, 1976; Doe and Goodman, 1985a; Doe, 1992). Because of this, neural precursor names in *Drosophila* have been chosen in order to indicate functional homology with those of the grasshopper (Goodman *et al.*, 1984; Doe, 1992; Jia *et al.*, 2002). However, this does not imply that each *Drosophila* neural precursor has a grasshopper

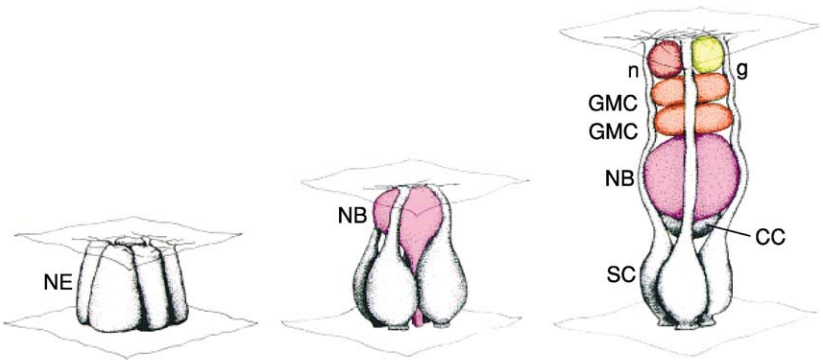

Figure 17 *Camera lucida* illustration of the delamination and the differentiation process of a neural precursor in the grasshopper. One neural precursor or neuroblast (NB) (pink) forms from a cluster of neuroectodermal cells (NE); the neuroblast enlarges and delaminates toward the interior of the embryo. Successive asymmetric divisions of the neural precursor give rise to ganglion mother cells (GMCs, orange), which divide once to produce sibling neurons or a neuron (n) and a glial cell (g) (red and yellow, respectively). In the grasshopper, sheath cells (SC) enwrap the progeny of each neural precursor. The grasshopper has one cell type not present in *Drosophila*, the cap cell (CC), which is attached to the ventral surface of every neural precursor. Ventral is down. (Modified from Doe, C.Q., Fuerstenberg, S., Peng, C.Y., **1998**. Neural stem cells: from fly to vertebrates. *J. Neurobiol. 36*, 111–127.)

equivalent. Both organisms have about 30 neural precursors per hemisegment, including a glial precursor that generates longitudinal glia and a MP2 precursor that produces the dMP2 and vMP2 neurons. Both in *Drosophila* and the grasshopper, neural precursors form in waves, with each new population of precursors arranged roughly in columns and rows (Doe and Goodman, 1985a; Doe, 1992).

Cell heterotopic transplantation experiments have shown that neural precursors are formed in the neuroectoderm before delamination (Prokop and Technau, 1994; Udolph *et al*., 1995), thus suggesting that positional information plays an essential role in neural precursor formation. Heterotopic transplantation between different Drosophilidae (*Drosophila melanogaster*, *D. virilis*, *D. hydei*, *D. pseudoobscura*, *D. latifasciaformis*, *D. buscii*) leads to results comparable to those obtained from intraspecific transplantations. Therefore, positional cues are conserved amongst these different species (Becker and Technau, 1990).

1.10.7.2. Neural Precursor Formation and Cell–Cell Interactions

The observation that the decision to adopt an epidermal or a neural fate is mediated by cell–cell interactions was first described in the grasshopper. Indeed, laser cell ablation experiments in this insect have shown that, while more cells than one in a specific region have the potential to form a neural precursor, the developing neural precursor inhibits its adjacent cells from developing as neural precursors (Taghert *et al*., 1984; Doe and Goodman, 1985a, 1985b). Thus, while under normal circumstances these adjacent cells develop as epidermoblasts, they adopt the neural fate when the neural precursor is killed. This demonstrates that the presumptive epidermoblasts are prevented by the neural precursor from adopting the neural fate. This process has been called lateral inhibition, and genetic studies in *Drosophila* have identified the Notch pathway as a major signaling process involved in cell fate choice (see Section 1.10.2.2.2).

1.10.7.2.1. Invariant neural precursor cell lineage The analysis of several identified grasshopper neural precursors has shown that each neural lineage is invariant and generates a specific set of neurons and/or glia (Bate and Grunewald, 1981; Goodman and Spitzer, 1979; Taghert *et al*., 1984), and this has allowed the establishment of a neural precursor map (Bate, 1976; Doe and Goodman, 1985a, 1985b). Subsequently, a similar map was also established in *Drosophila* (see Section 1.10.2.3). Some of the lineages in these two insects show similarities; thus, for example, both in the grasshopper and in *Drosophila*, the first GMC from NB1-1 always divides to produce the aCC and pCC motorneurons (Goodman and Spitzer, 1979; Udolph *et al*., 1993).

While embryonic thoracic and abdominal segments of hemimetabolous insects have more neural precursors present in the thoracic segments than in the abdominal ones (Bate, 1976; Doe and Goodman, 1985a; Booker and Truman, 1987), in the holometabolous *Drosophila* embryo, the neural precursor patterns in the thoracic and abdominal segments look very much the same (Doe, 1992). This implies that hemi- and holometabolous insects employ distinct mechanisms in order to produce segmental cell diversity: in the first case, cell diversity is triggered

by the production of segment-specific neural precursors, whereas in the second one, the difference in the number and/or the type of neuron and glial cell between thoracic and abdominal segments is a consequence of segment-specific neural precursor lineages. In both cases, these segmental differences are due to the action of homeotic genes that control differentiation of the neurogenic region in hemimetabolous insects and segment-specific lineage in holometabolous insects (see Section 1.10.3.1.1).

1.10.7.3. Conservation of Proneural Activity during Evolution

In general, the mechanisms involved in insect neurogenesis appear to be well conserved during evolution. How could one explain such conservation?

In *Drosophila*, the proneural genes, including the genes of the *Achaete–Scute Complex* (*ac*, *sc*, *l'sc* and *ase*), confer neural potential to cells and/or specify neuronal subtypes (Brunet and Ghysen, 1999; Chan and Jan, 1999). Because *AS-C* members are involved in the initiation of nervous system development in invertebrates and vertebrates (Section 1.10.2.2.1), the study of these genes has allowed the understanding of the evolution of development of the arthropod nervous system (Skaer *et al*., 2002).

Phylogenetic trees constructed by amino acid sequence comparison of the products encoded by the *achaete–scute* orthologs strongly suggest that the four *Drosophila* genes have arisen from three independent duplication events during insect evolution (Skaer *et al*., 2002). In contrast, *Tribolium castaneum* (Coleoptera) and *Anopheles gambiae* (an, "early" dipteran) contain a single proneural *ac-sc* like gene (Wulbeck and Simpson, 2002; Wheeler *et al*., 2003), whereas *Ceratitis*, a more recently evolved dipteran, contains two proneural *ac–sc* like genes (Wulbeck and Simpson, 2000). Thus, a duplication of an ancestral proneural *ac–sc* like gene has occurred within the dipteran lineage prior to the apperance of *Ceratitis*.

The *ase* gene is the only member that is expressed only in the neural precursors (Brand *et al*., 1993; Jarman *et al*., 1993). Within the complex, the *ase* orthologs form a group that is clearly separated from the other genes, suggesting that the duplication of an ancestral gene has given rise to *ase* and to a gene from which *l'sc*, *sc*, and *ac* evolved subsequently. Actually, it appears that the last common ancestor of arthropods contained a single prototypical *ac–sc* like gene that carried out both proneural and *ase* functions (Skaer *et al*., 2002). The duplication giving rise to *ac* and *sc* is the most recent event. Additional evidence for this is the observation that the *ac* and *sc* genes of *Drosophila* share *cis*-regulatory elements, are almost always coexpressed, and their products are functionally redundant (Rodriguez *et al*., 1990; Martinez and Modolell, 1991; Skeath and Caroll, 1991; Cubas and Modolell, 1992; Gomez-Skarmeta *et al*., 1995). After duplication, the new genes have acquired individual expression patterns but, in *Drosophila*, their products can compensate for one another, showing that a functional conservation has been maintained during evolution.

While *ac*, *sc*, and *l'sc* have the potential to induce neural precursor formation, only *ac* or *sc* can promote a correct gene expression profile and cell division pattern of the MP2 precursor (Parras *et al*., 1996; Skeath and Doe, 1996), suggesting that *ac* and *sc* control both the formation and invidual fate specification of neural precursors. Recently, it was shown that the single *ac–sc* like ortholog identified in the red flour beetle *T. castaneum* has conserved its proneural function, but is unable to allocate specific identity to neural precursors (Wheeler *et al*., 2003). This suggests that the ability of *ac* and *sc* to control specification of neural precursors represents a recent evolutionary specialization within Diptera.

1.10.8. Conclusion and Perspectives

The nervous system represents the most complex tissue in multicellular organisms. The sophisticated network of neurons and glia generated by neural stem cells allows organisms to respond and adapt to the numerous internal and external stimuli they encounter constantly during life. Characterizing the molecular and the cellular cues underlying the differentiation of the nervous system has a dual goal. First, it should allow us to understand how complex tissues are built during development and preserved during ontogenesis. Second, it should also have implications in the development of targeted therapeutic strategies for brain cancer and neurodegenerative diseases. The evolutionary conservation of the developmental strategies makes it likely that the use of a simple genetic model like *Drosophila* will help us to unravel the molecular and cellular basis of vertebrate neural development.

One of the most challenging issues for the next generation of drosophilists will be to follow the different steps that lead to nervous system differentiation *in vivo*, and to combine real-time observations with genetic dissection approaches. The ultimate goal will be to integrate the inter- and intracellular signaling pathways that coordinate

the establishment of the highly sophisticated neural network.

1.11 Development of Insect Sensilla

V Hartenstein, University of California, Los Angeles, CA, USA

1.11.1. Structure of Insect Sensilla

1.11.1.1. General Remarks

The sensory system of insects (see also **Chapter 1.12**) is comprised of a large number and great diversity of small organs, called sensilla, which form part of the epidermis. The central component of each sensillum is one or more sensory neurons, which respond to a specific stimulus. The sensory neuron(s) is embedded in a stimulus-receiving apparatus formed by modified epidermal cells, summarily called accessory cells. Stimulation of the sensory neurons results in an action potential that is transmitted via the axon towards the central nervous system (CNS). The special morphology and molecular composition of sensory neurons and accessory cells adapt sensilla towards the reception of a wide range of stimuli, including mechanical stimuli (touch, pressure, vibration, stretching), chemical stimuli (olfactory, gustatory), temperature, and humidity. Most sensilla have contact to the external surface; some sensillum types, in particular stretch receptors, are attached to the inner surface of the body wall or internal organs. The complex morphology of mature insect sensilla has been surveyed in many comprehensive reviews (e.g., Keil and Steinbrecht, 1984; Zacharuk, 1985; Barth *et al.*, 1986; Keil, 1997, 1998; Eguchi and Tominaga, 1999) and can only be touched upon briefly in this chapter whose focus is development.

Despite their great diversity, sensilla are built according to only two main schemes (**Figure 1**). The large majority of sensilla (type I) contain bipolar sensory neurons surrounded by a pair of inner and outer accessory cells. The inner accessory cells form a sheath around the dendrite and, variably, the

A list of all genes and proteins discussed in this chapter is provided in the Appendix.

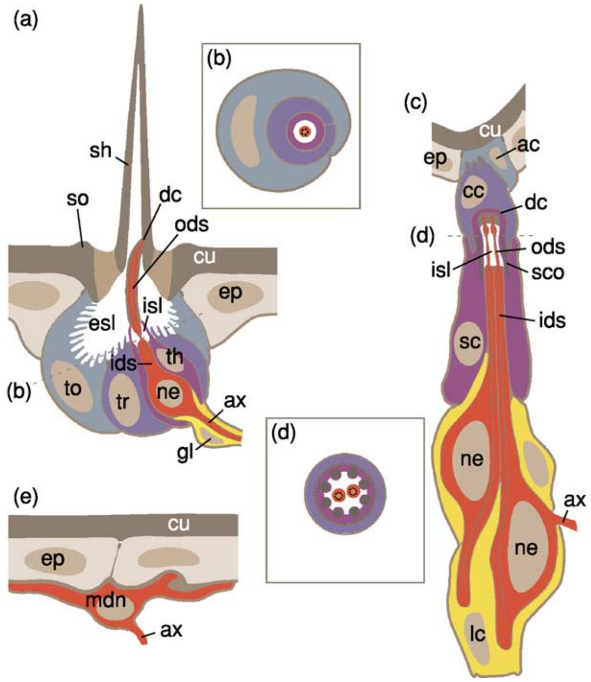

Figure 1 Structure of mature insect sensilla. Schematic sections of the three main classes of sensilla. In this and all following schematics each sensillum cell is consistently rendered in its own color. (a, b) External sensillum. (c, d) Chordotonal organ. (a) and (c) show longitudinal sections; transverse sections at the level indicated by dotted lines are depicted in (b) and (d), respectively. (e) Multidendritic neuron. ac, attachment cell; ax, axon; cc, cap cell; cu, cuticle; dc, dendritic cap; ep, epidermal cell; esl, external sensillum lymph space; gl, glial cell; ids, inner dendritic segment; isl, internal sensillum lymph space; lc, ligament cell; mdn, multidendritic neuron; ne, bipolar sensory neuron; ods, outer dendritic segment (modified cilium); sc, scolopale cell; sco, scolopale; so, sensillum socket; th, thecogen cell; to, tormogen cell; tr, trichogen cell.

soma/proximal axon of the sensory neuron(s). The outer accessory cells are arranged concentrically around the inner ones (Figure 1b). They form processes that, in case of sensilla situated at the surface (external sensilla or ES organs), secrete cuticle in the shape of hairs or bristles (Figure 1a). Outer accessory cells of subepidermal stretch receptors, called chordotonal organs, form ligaments that attach the sensory neuron(s) to the bodywall (Figure 1c and d).

The second major type of sensilla (type II) consists of subepidermally located multipolar (multidendritic) neurons which are either "naked" (Figure 1e) or are associated with variable (and largely unexplored) types of accessory cells. As will be presented in more detail below, evidence has been accumulated in *Drosophila* that type I and type II sensilla form part of the same lineage.

1.11.1.2. External Sensilla

External sensilla possess an external cuticular shaft of various size and shape, and a socket or joint that anchors the process in the surrounding epidermis (Figures 1a and 2a). The shaft and socket are formed by the outer accessory cells, called trichogen and tormogen cell, respectively. Trichogen and tormogen cells are specialized epidermal cells that, when viewed from their apical surface, are folded in the shape of a doughnut around an inner cylinder that consists of the sensory neuron and inner accessory cells (Figure 1b). These latter cells form the part of an external sensillum that cannot be seen at the surface. Their cell bodies (somata) are sunken beneath the level of neighboring epidermal cells and of the outer accessory cells (Figures 1a and 2e).

The somata of sensory neurons are spindle-shaped, bipolar cells (type I sensory neurons) whose dendrites extend apically through the opening provided by the trichogen cell (Figure 1a). The proximal part of the dendrite close to the soma, called inner dendritic segment, ultrastructurally resembles the soma itself (Figures 1a and 2f). The inner segment ends level with the apical surface of the surrounding trichogen cell. Beyond this level, the dendrite continues as the outer segment, which constitutes a modified cilium (Figures 1a and 2e). Like a typical cilium, the outer segment of a sensory dendrite contains an axoneme, a circular array of microtubules (Figure 2e). These microtubules emanate from a basal body which is located at the narrow transition between the inner and outer dendritic segment (Figures 1a and 2f). Basally, bundles of microtubules and microfilaments, the so-called rootlet filaments (Figure 2f), anchor the basal body to the cytoskeleton of the sensory neuron. Apically, the outer dendritic segments show variable specializations related to stimulus transduction. In mechanoreceptive sensilla, outer segments end as an enlarged bulb, called the tubular body, which contains stacks of microtubules (Figure 2c and f). Depending on sensillum modality, the outer segment of sensory dendrites extends into the lumen of the sensory process (Figure 2d) or terminates at its base (Figures 1a and 2c; see below).

The inner accessory cells form glia-like sheaths around the sensory neurons. One cell, called the thecogen cell, is located apically of the neuron, that is, between the neuronal soma and the trichogen cell. The thecogen cell forms a thin, cylindric sheath around the dendrite (Figures 1a, b, and 2e, f). This process secretes an extracellular matrix, the dendritic cap, around the tip of the outer dendritic segment (Figures 1a and 2c, f). The second, more basal inner accessory cell, which can be missing in many

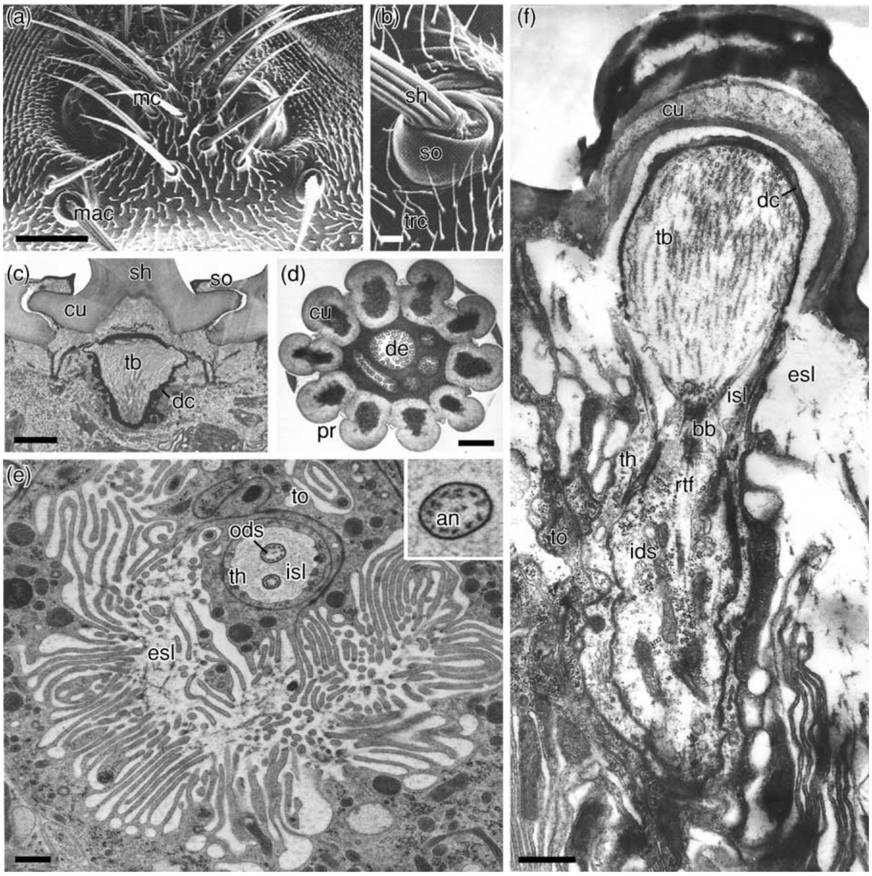

Figure 2 Structure of mature insect external sensilla. (a) Scanning electron micrograph of dorsal head capsule of *Drosophila*, showing arrays of small mechanoreceptive bristles (mc, microchaetes) and large bristles (mac, macrochaetes). (b) Higher magnification of basal part of macrochaete with bristle shaft (sh) and socket (so). Sensory bristles are surrounded by small, non-innervated trichomes (trc) formed by epidermal cells. (c, d) Transmission electron micrographs (TEMs) of apical cross-sections of cricket mechanosensory sensillum (c) and chemosensory sensillum (d). In (c), the tip of outer dendritic segment forms a bulbar thickening, the tubular body (tb) that is surrounded by the dendritic cap (dc). The tubular body terminates underneath the cuticle of the sensillum shaft (sh). Dendrites of chemosensory neurons (de in (d)) extend into the lumen of the shaft, which connects to the outside via numerous pores (pr). (e) TEM of basal cross-section of mechanosensory sensillum, showing the internal sensillum lymph space (isl), microvilli-lined external sensillum lymph space (esl), thecogen cell (th), and ciliary outer dendritic segments (ods). Inset shows ciliary dendrite with axoneme (an) at higher magnification. (f) TEM of longitudinal section of *Drosophila* campaniform sensillum, showing dome-shaped cuticular sensillum shaft (cu), tubular body (tb), dendritic cap (dc), basal body (bb), rootlet fiber (rtf), and inner dendritic segment (ids) surrounded by thecogen cell (th). Scale bar = 10 μm (a); 1 μm (b–f). ((a, b): Reproduced with permission from Bang, A.G., Posakony, J.W., **1992**. The *Drosophila* gene *Hairless* encodes a novel basic protein that controls alternative cell fates in adult sensory organ development. *Genes Devel. 6*, 1752–1769; © Cold spring Harbor Laboratory Press. ©: Reproduced from Keil, T.A., **1997**. Mechanosensitive and olfactory sensilla of insects. In: King, R.C., Akai, H. (Eds.), Insect Ultrastructure, vol. 2. Plenum, New York, pp. 477–516.)

external sensilla, represents a *bona fide* glial cell (on the basis of its expressing glial specific markers; Lai and Orgogozo, 2004) that ensheaths part of the sensory soma and axon (**Figure 1a**).

Two cavities filled with hemolymph of special ionic composition surround the dendrite and are crucial for the generation of a receptor potential that takes place in the dendrite (Thurm and Kueppers, 1980). The first cavity, called the external sensillum lymph space (ESL), is formed in the interior of the bristle, where the apical membranes of the trichogen and tormogen cells retreat from the cuticle (**Figures 1a** and **2e**). The ESL is exterior to the thecogen cell and the dendritic sheath. A second, smaller cavity, the inner sensillum lymph space (ISL), forms in between thecogen and sensory dendrite, near the junction of the inner and outer dendritic segments (**Figures 1a** and **2e, f**).

External sensilla present many different morphologies adapted to their modality. Structurally, one distinguishes between hairs (sensilla trichoidea; **Figure 3a** and **b**), bristles (sensilla chaetica; **Figure 3c**),

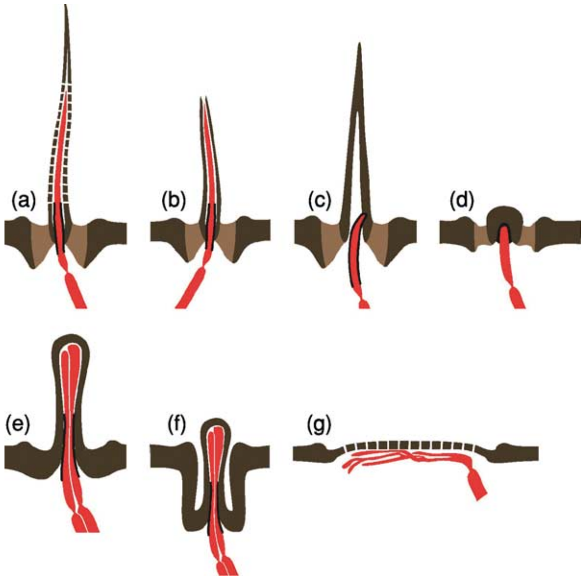

Figure 3 Morphological classification of external sensilla. (a) Multiporous trichoid sensillum (olfactory); (b) uniporous trichoid sensillum (gustatory); (c) aporous bristle (mechanosensory); (d) campaniform sensillum (external stretch receptor); (e) basiconical sensillum (hyogro/thermosensory); (f) coeloconical sensillum (hygro/thermosensory); and (g) hair plate (chemosensory).

domes (sensilla campaniformia; Figure 3d), cones (sensilla basiconica; Figure 3e), sunken cones (sensilla ceoloconica; Figure 3f), and plates (Figure 3g).

Sensilla campaniformia act as external stretch receptors, sensing deformations of the surrounding cuticle. In these sensilla, the dendritic tip is inserted into the apex of the cuticular process, such that cuticular stretching will lead to pressure on the outer dendritic segment, which elicits the receptor potential. Hairs and bristles act as receptors for touch and air flow. Here, the dendritic tip is attached to the base of the hair or bristle and reacts to deflection of these structures (Figure 3c). Cones and sunken cones (Figure 3e and f) are often receptors of temperature and humidity (Altner *et al.*, 1981). The outer dendritic segments fill the lumen of the cone (Figure 3e and f) and are compressed by dilation or contraction of the cone cuticle that occurs in response to changes in heat and moisture.

Both bristle/hair-shaped and cone-shaped sensilla can also act as chemoreceptors. Morphologically, chemoreceptors can be identified by pores in the cuticle which admit the chemical stimuli. Typically, contact chemoreceptors (gustatory) are characterized by a single opening at the tip of the process (uniporous; Figure 3b), whereas olfactory chemoreceptors have multiple pores all along the shaft of the process (Altner, 1977; see **Chapter 1.12**; Figure 3a; see also Figure 2d). In many sensilla, multiple neurons with different sensory modalities are clustered together. In view of the enormous diversity of insect morphology and ecology, this rough classification covers only the major classes of sensilla.

1.11.1.3. Chordotonal Organs

Chordotonal organs are subepidermal stretch receptors, which nevertheless share numerous structural and developmental characteristics with external sensilla (Moulins, 1976). Chordotonal organs typically consist of multiple units called scolopidia. Each scolopidium has a bipolar sensory neuron with a short apical dendrite and a basal axon (Figure 1c). Outer dendritic segments of chordotonal neurons differ from their counterparts in external sensilla in several aspects. The former are typically shorter and straighter (stiffer) than the latter, and have a conspicuous subapical "swelling" called the ciliary dilation (Figure 4a). The anchoring rootlet filaments extending from the basal body at the junction between inner and outer dendritic segment are longer and more massive than their counterparts in external sensilla (Figure 4c and d). The dendrite is encapsulated by the scolopale cell, homologous to the thecogen cell of external sensilla (Figures 1c, d and 4a–c). The scolopale cell forms the dendritic cap around the tip of the dendrite (Figure 4a); further basally, it produces the scolopale, a conspicuous circular array of intracellular, tubulin-rich rods surrounding the dendrite (Figure 4a–c). Between scolopale and dendrite the inner receptor lymph space opens. Basally, the sensory neuron is embedded in the ligament cell which attaches at the epidermis (Figure 4d). The ligament cell, which on the basis of recent findings can be homologized to the glia cell of an external sensillum (Jones *et al.*, 1995; Lai and Orgogozo, 2004; see below), is missing in some chordotonal organs.

The outer accessory cells of a chordotonal organ are represented by the cap cell and the attachment cell which connect the scolopale and the dendrite enclosed in it to the epidermis (Figures 1c and 4a). In this manner, the scolopidium is anchored at two points to the epidermis. Stretching of the epidermis will cause a lengthening of the scolopale, which compresses the dendrite and elicits a receptor potential (Moulins, 1976; McIver, 1985).

1.11.1.4. Type II Multidendritic Sensilla

Besides the sensilla that are innervated by bipolar neurons, the insect sensory system comprises another set of multidendritic subepidermal neurons which act as receptors for pressure and stretch (Finlayson, 1976; Frye, 2001). A subset of these sensory neurons is

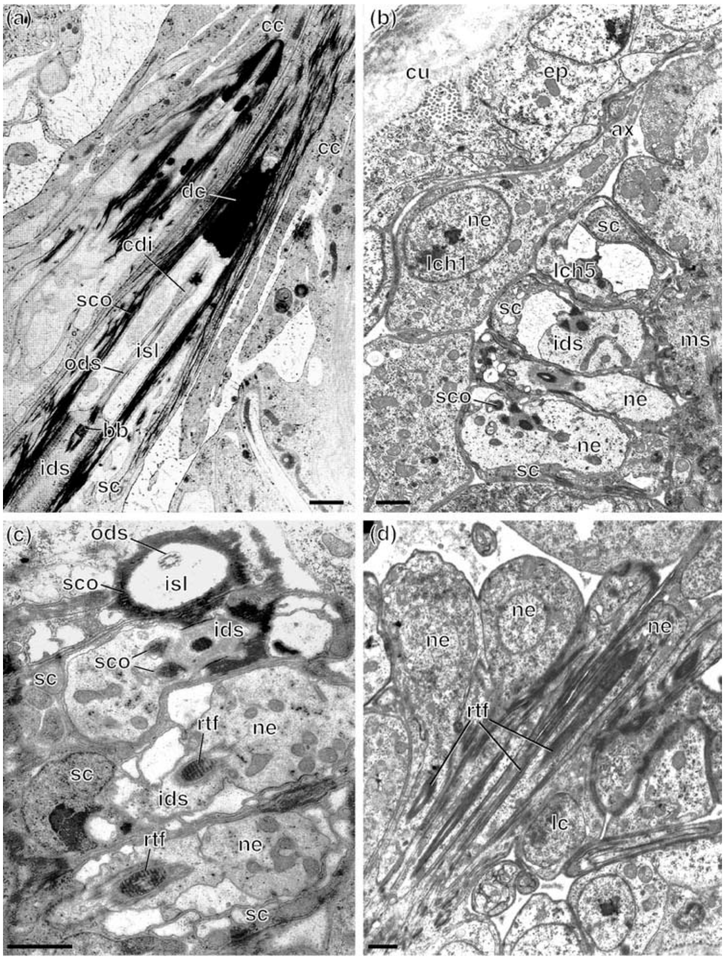

Figure 4 Structure of the mature chordotonal organ. TEMs of sections of chordotonal organs in the cricket (a) and the *Drosophila* larva (b–d). (a) Longitudinal section of apices of two scolopidia, showing inner dendritic segment (ids) and outer dendritic segment (ods). Surrounding the dendrite is the scolopale cell (sc), which forms the scolopale rods (sco) and, at the tip of the dendrite, the dendritic cap (dc). The scolopale cell is inserted at the cap cell (cc). Note the characteristic subapical ciliary dilation (cdi) of the dendrite. (b) Transverse section of lateral pentascolopidial (lch5) and monoscolopidial (lch1) chordotonal organs, which occupy the narrow niche between epidermis (ep) and somatic musculature (ms). The lch5 is sectioned at a level at which the neuronal cell body (ne) continues as the inner dendritic segment (ids). Note the tips of scolopale rods (sco) surrounding dendrite. The lch1 is sectioned at a more basal level where the soma produces an anteriorly directed axon (ax). (c) Tilted transverse section of lch5, showing profiles of scolopidia at different apico-basal levels. The most anterior scolopidium (top) is sectioned furthest apically, showing outer dendritic segment (ods) and scolopale (sco). At this apical level, the scolopale rods have merged into a ring-like structure. The adjacent scolopidium is sectioned at a more basal level near the transition of inner (ids) and outer dendritic segment. The scolopale (sco) is broken up into individual rods. Continuing basally (downwards in the panel) one sees the inner dendritic segment (ids) containing the massive rootlet filaments (rtf). (d) Longitudinal section of base of lch5, showing sensory cell bodies (ne) surrounded by sheaths formed by the ligament cells (lc). Note the thick rootlet filaments (rtf) which continue all the way from the dendrite downwards into the basal extension of the neuronal cell bodies. Scale bar = 1 μm. ((a): Reproduced with permission from Keil, T.A., **1997**. Functional morphology of insect mechanoreceptors. *Microsc. Res. Tech. 39*, 506–531; © John Wiley & Sons, Inc.)

accompanied by specialized ligament cells by which they stretch out alongside muscles; examples are the wing hinge stretch receptors and pleural stretch receptors. Most multidendritic neurons are naked, extending complex dendritic arbors at the basal surface of the epidermis (Figure 5a). These neurons, which have been identified in soft-bodied insects (i.e., mostly larval stages of holometabolans) are called dendritic arbor (*da*) neurons. In *Manduca* and *Drosophila*, four classes (α, β, γ, and δ) with different dendritic complexity, axonal termination, and physiological properties were defined (Grueber *et al*., 2001, 2002; Figure 5b). Members of one class completely tile the epidermis. Thus, dendritic branches of a given *da* neuron form a dense mesh in a given domain of the epidermis. Another *da* neuron of the same class innervates a domain that is contiguous, yet nonoverlapping with the first one. In this manner, the entire epidermis is completely covered with the innervation domains of the *da* neurons of a given class.

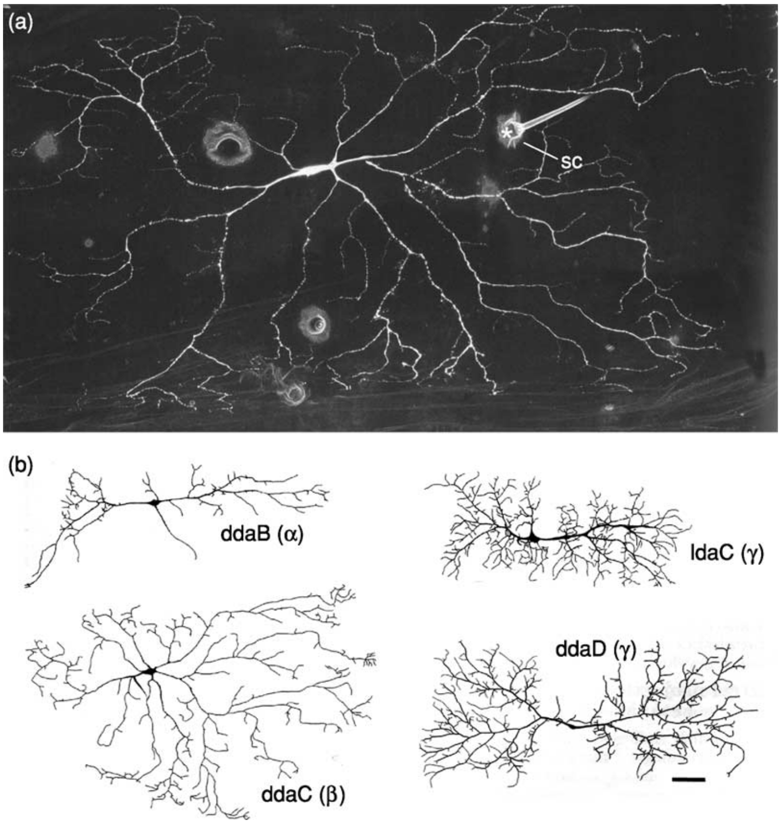

Figure 5 Multidendritic (Type II) neurons. (a) Dye filling of subepidermal multidendritic neuron (β class) in *Manduca*. (b) Line drawings of multidendritic neurons (ddaB, ddaC, ddaD, ldaC; For nomenclature, see **Figure 7a**) that represent the four morphologically defined classes (Grueber *et al.*, 2001). Neurons of class α have a small dendritic arbor with a few branches. Class β neurons are small, but possess highly branched dendrites. Class γ is large and possesses low branch density; δ is large and has high branch density. Scale bar = 100 μm. ((a, b): Reproduced from Grueber, W.B., Graubard, K., Truman, J.W., **2001**. Tiling of the body wall by multidendritic sensory neurons in *Manduca Sexta*. *J. Comp. Neurol. 440*, 271–283.)

1.11.1.5. Pattern of Sensilla

The distribution of sensilla of different structures and modalities is extremely diverse among insects, and only a few generalizations will be made here. Bristle and hair-shaped mechanoreceptors can occur everywhere on the trunk, head, and appendages. These mechanoreceptors typically form large arrays of more or less evenly spaced elements, such as those shown for the dorsal head of *Drosophila* (**Figure 2a**) and the trunk of juvenile *Acheta* (**Figure 6a**). External stretch receptors (campaniform sensilla) form tight clusters on some appendages (e.g., halteres in Dipterans; **Figure 6b**), but also occur as scattered individual sensilla on the trunk.

Chordotonal organs and certain types of type II stretch receptors form clusters laterally and ventrolaterally. In the thorax and head, these lateral chordotonal organs form stretch receptors at the base of the appendages. Large arrays of chordotonal organs in the antenna and (in some insect groups) the thorax have adopted an auditory function. In these cases, a large area of surrounding cuticle and inner tracheal sacs is incorporated into a complex, multichambered structure, called Johnston's organ in the antenna, and the tympanal organ in the leg of many insects, that receives and amplifies sound waves (reviews: Yager, 1999; Caldwell and Eberl, 2002).

Chemoreceptors are found on the appendages and in the mouth cavity (see **Chapter 1.12**). Olfactory bristles and cones are clustered on the antenna and maxillary palp; gustatory hairs occur in the pharynx, but also on the wings and legs. Thermo- and hygroreceptory cones have been described on the antenna of some insects (**Figure 6c**), but also occur on the trunk of various insect larvae (**Figure 6d**).

An impression of the variability of sensillum number and distribution can be gained from **Figure 6e** which compares the pattern of external sensilla found in the abdomen of different insect groups (Green and Hartenstein, 1997). The only feature most of these patterns have in common is that they form a rather narrow vertical array located in the center or somewhat posteriorly to the center of each segment. (As will be discussed in a later section, this

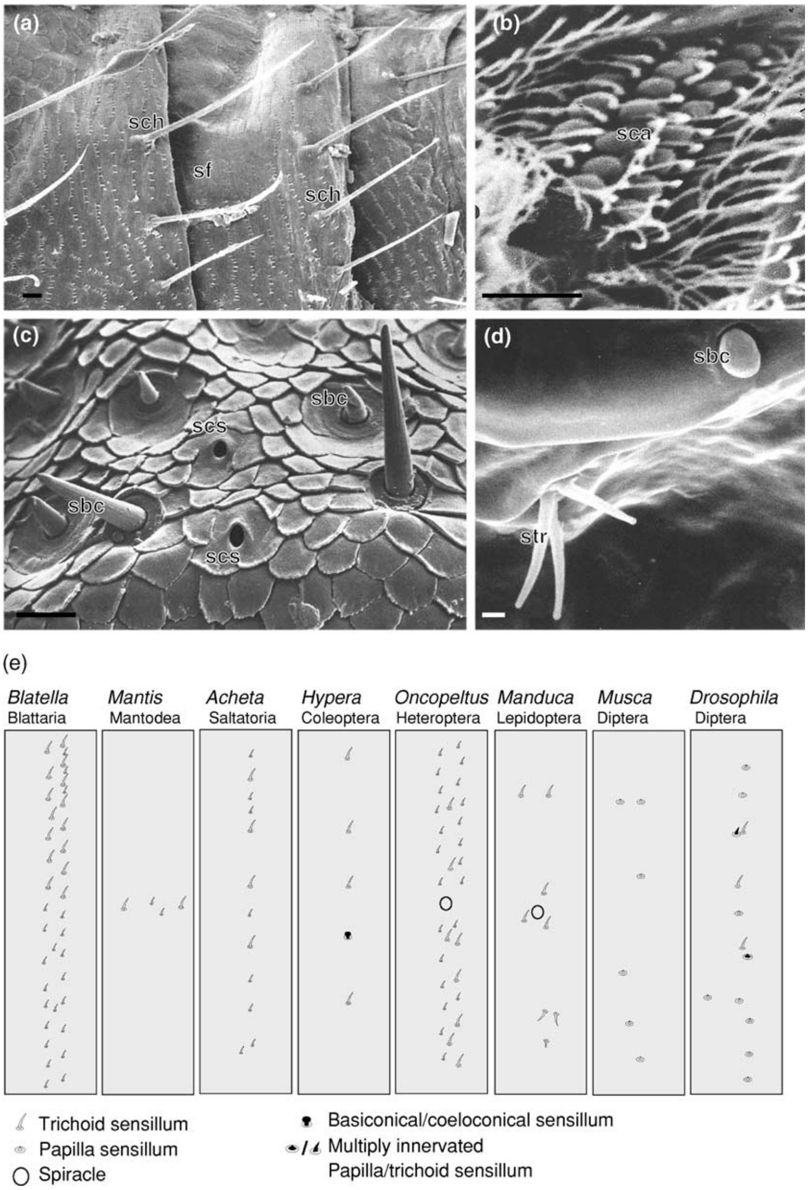

Figure 6 Pattern of external sensilla in different insect groups. (a–d) represent SEMs of parts of the bodywall. (a) Linear arrays of bristles (sensilla chaetica, sch) in the abdomen of juvenile *Acheta*. sf, segment boundary. (b) Campaniform sensilla (sca) on the base of the haltere of adult *Drosophila*. (c) Basiconical (sbc) and coeloconical (scs) sensilla on the antenna of *Locusta*. (d) Basiconical sensillum (sbc) and trichoid sensilla (str) on the ventral thorax of larval *Drosophila*. (e) Schematic depiction of sensillum pattern in eight different insect species whose names and taxa are given at the top of panel. Each rectangle represents one abdominal hemisegment, with the dorsal midline at the top and the ventral midline at the bottom. Different types of sensilla are indicated by different graphic symbols, as shown in key at the bottom of figure. Scale bar = 10 μm (a–c); 1 μm (d). ((a, d, e): Green, P.J., Hartenstein, V., **1997**. location, which is also found in the *Drosophila* larva, can be explained in terms of the Wingless morphogen gradient.) However, the types of sensilla vary radically. In *Blatella* and *Oncopeltus* one encounters several rows of trichoid sensilla; in most dipteran larvae, interspersed trichoid sensilla, papilla sensilla (which could be external stretch receptors, similar to campaniform sensilla) and a few conical sensilla form one row; in some dipterans, only papilla sensilla or conical sensilla are found.

Despite the diversity of sensillum patterns in the mature animal (be it larval or adult), there seems to be a high degree of similarity between the patterns in which sensilla assemble in early embryos. This

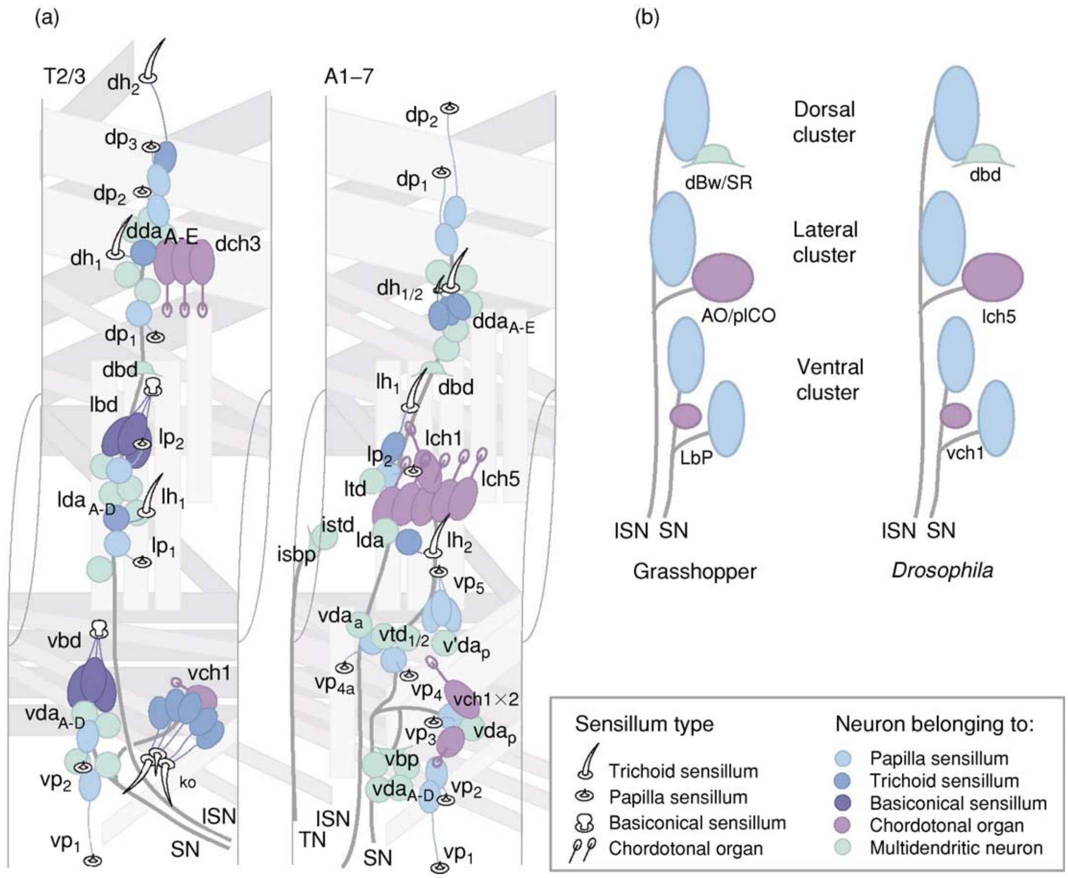

Figure 7 Pattern of sensilla in embryonic *Drosophila* and grasshopper. (a) Schematic drawing of a thoracic (T2/3) and abdominal (A1–7) hemisegment in which sensilla and muscle fibers are depicted. For both hemisegments, the dorsal midline is at the top, the ventral midline at the bottom, anterior is to the left. The location of sensilla is indicated by graphic symbols (see key at bottom right of figure). Somatic muscle fibers are shown in gray. For details on the pattern see text. (b) Simplified pattern of sensillum precursors in embryonic grasshopper and *Drosophila*. Colored profiles show sensory neurons belonging to external sensilla (blue), chordotonal organs (violet), and multidendritic neurons (green). In both species one sees a dorsal, lateral, and ventral cluster of sensillum precursors. Dorsal and lateral sensilla are inervated by the intersegmental nerve (ISN), ventral ones by the segmental nerve (SN). The elements of the sensillum pattern identified by color labeling can be homologized. AO/plCO, lateral chordotonal organ (grasshopper); dbd, dorsal bidenritic neuron (stretch receptor); dBw/SR, wing hinge receptor (grasshopper); dch3, dorsal triscolopidial chordotonal organ; $dda_{A\text{-}E}$, dorsal multidenritic neurons; $dh_{1\text{-}2}$, dorsal hairs (trichoid sensilla); $dp_{1\text{-}3}$, dorsal papilla sensilla; isbp, istd intersegmental multidendritic neurons; ISN, intersegmental nerve; lbd, lateral basiconical sensillum; LbP, ventral chordotonal organ (grasshopper); lch1, lateral monoscolopidial chordotonal organ; lch5, lateral pentascolopidial chordotonal organ; $lda_{A\text{–}D}$, ltd lateral multidendritic neurons; lh_1, lateral hair (trichoid sensillum); $lp_{1\text{-}2}$, lateral papilla sensilla; SN, segmental nerve; TN, transverse nerve; vbd, ventral basiconical sensillum; vch1, ventral monocolopidial chordotonal organs; $vda_{A\text{–}D}$, vbp, vda_a, vda_p, vtd1-2, $v'da_p$, ventral multidendritic neurons; $vp_{1\text{-}5}$, ventral papilla sensilla. ((a) Adapted from Campos-Ortega, J.A., Hartenstein, V., **1997**. The Embryonic Development of *Drosophila melanogaster*, 2nd edn. Springer, Berlin; (b) Adapted from Meier, T., Chabaud, F., Reichert, H. **1991**. Homologous patterns in the embryonic development of the peripheral nervous system in the grasshopper *Schistocerca gregaria* and the fly *Drosophila melanogaster*. *Development 112*, 241–253.)

conclusion can be drawn from the study of Meier *et al.* (1991) who compared the embryonic formation of the peripheral nervous system in the grasshopper and *Drosophila*.

The late embryonic sensillum pattern of *Drosophila*, which will be referred to repeatedly in later sections, is shown in detail in **Figure 7a**. Sensilla of different types form a dorsal, lateral, and ventral cluster (Campos-Ortega and Hartenstein, 1985; Ghysen *et al.*, 1986; Bodmer and Jan, 1987). Dorsal and lateral sensilla project their axons via the intersegmental nerve, whereas ventral sensilla project through the more posterior segmental nerve.

In the abdominal segments, the dorsal cluster comprises two closely spaced trichoid sensilla (dh_1 and dh_2) and two papilla sensilla (dp_1 and dp_2), as well as six multidendritic type II sensory neurons ($dda_{A\text{-}E}$, dbd). The lateral cluster contains two hairs (lh_1, lh_2), one papilla sensillum (lp_2), two multidendritic neurons (ltd, lda), and two chordotonal organs (lch5 with five scolopidia, and lch1 with one scoplopidium). The ventral cluster has

six papilla sensilla (vc1-3, vc4 and vc4a, vc5), ten multidendritic neurons ($vda_{A\text{-}D}$, vda_p, $v'da_p$, vda_a, vtd1-2, vbp), and two chordotonal organs (vch1).

The thoracic pattern of sensilla is similar, with several notable exceptions. The lateral chordotonal organ has shifted towards dorsally (dch3); a multiply innervated conical sensillum, not found anywhere in the abdomen, forms part of the lateral and ventral thoracic cluster (lbd and vbd, respectively); and a star-shaped array of three hair sensilla, the so-called Keilin's organ, is found in the ventral cluster.

If one compares the *Drosophila* embryonic pattern to that in grasshopper embryos, the similarities are striking (**Figure 7b**). In both, embryonic sensilla form three clusters, of which the dorsal and lateral ones project through the intersegmental nerve, and the ventral one through the segmental nerve (Meier *et al*., 1991). A prominent type II stretch receptor (dbd in *Drosophila*, dBw or wing hinge receptor in grasshopper) forms part of the early dorsal cluster and is one of the pioneers of the intersegmental nerve. Laterally chordotonal organs in early clusters of both species; and a ventral chordotonal organ (LbP in grasshopper, vch1 in *Drosophila*). Great similarities also exist in the pattern of multidendritic *da* neurons (subepidermal stretch receptors) between the lepidopteran *Manduca* and *Drosophila* (Grueber *et al*., 2001, 2002).

1.11.1.6. Sensillum Development: Overview

Insect sensilla have attracted the attention of developmental biologists since the early days of experimental biology. It was recognized that, in many sensilla, all cells originate from a single cell, the sensillum progenitor cell (SOP; **Figure 8**), which divides in a stereotyped pattern. SOPs can be easily observed because of their size and staining properties, and they became a classical paradigm for the study of cell fate determination. It was (rightly) assumed that intrinsic factors, expressed by the SOP and forwarded in a specific pattern to its progeny, must act as determinants of the different sensillum cell fates. This assumption has turned out to be correct, and several specific molecules involved in sensillum fate determination have been identified. Insight has also been gained into the cell biological mechanism by which these determinants are assigned to the proper cells during SOP mitosis. Finally, begun to understand the connection between cell fate determinants, which are transcription factors acting in the nucleus of a cell, and the way in which these molecules effect changes in cell structure during sensillum differentiation.

The following sections of this chapter attempt to provide an overview of sensillum development and the mechanisms guiding it. First, it will be seen how SOPs of different types of sensilla are specified, and what mechanisms are responsible for the sensillum pattern. Next, the SOP mitoses generating the different SOPs will be followed. The main focus of attention during this phase in sensillum development rests on the mechanism controlling the mitotic spindle and thereby influences theexpression of sensillum cell type specific determinants in the proper cells. Furthermore, cell–cell signaling events among the sensillum cell precursors, representing the second source of information guiding sensillum cell fate, will be considered. Next, the morphological aspects of sensillum differentiation, consisting of stereotyped changes in cell shape and position, will be analyzed. The last section will look beyond insect sensilla and address the evolutionary connections between these organs and sensory structures in other animal groups.

1.11.2. The Specification of SOPs

1.11.2.1. General Characteristics of SOPs

SOPs are derived from the embryonic ectoderm and, in holometabolous insects such as *Drosophila*, from the imaginal discs that form the adult body (see also **Chapter 1.10**). Structurally, SOPs can be distinguished from their epidermal neighbors by their larger size, more basal nucleus, and protracted proliferation that results in the production of sensillum lineages (Cubas *et al*., 1991; Skeath and Carroll, 1991; Hartenstein *et al*., 1994; LeBorgne *et al*., 2002; **Figure 8a** and **b**). The pattern of SOPs largely reflects the later pattern of sensilla they give rise to; following SOP division, SOP cells remain at the location where they were born and differentiate. Only the position of somata of neurons and inner accessory cells occasionally shifts away from the location where these cells were initially placed into the ectoderm, due to the lengthening of the dendrite and dendritic sheath.

1.11.2.2. Proneural Clusters and Proneural Genes

SOPs are selected from the ectoderm in a two-step mechanism (**Figure 8c**). First, relatively large clusters of contiguous ectodermal cells, called proneural clusters, become competent to develop as SOP. In some cases, such as the large bristles (macrochaetes) on the *Drosophila* notum (**Figure 8a** and **b**), each sensillum is represented by a proneural cluster (Cubas *et al*., 1991). More typically, arrays of closely spaced sensilla, such as the microchaetes on the notum, or the sensilla on the antenna, legs, and wing margin, come from stripe-like proneural domains (**Figure 8b**).

Proneural clusters can be visualized by the expression of a family of transcription factors called proneural genes (Campos-Ortega, 1997; Hinz, 1997; Modolell, 1997; Caldwell and Eberl, 2002; Skaer

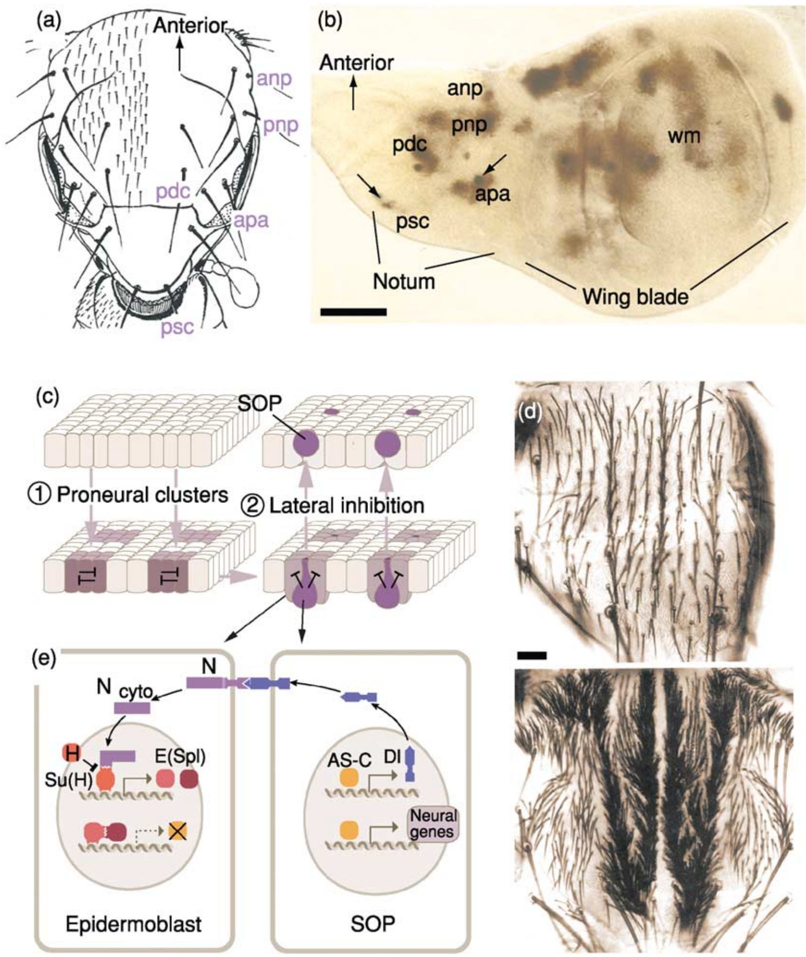

Figure 8 Genetic control of sensillum patterning. (a) Schematic drawing of *Drosophila* notum (dorsal thorax) indicating invariant pattern of macrochaetes. Some of the macrochaetes are identified individually. anp, anterior notopleural; apa, anterior postalar; pdc, posterior dorsocentral; pnp, posterior notopleural; psc, posterior scutellar. (b) Expression of the proneural gene *scute* (blue) in wing imaginal disc. SOPs are double-labeled (brown) by expression of a reporter gene construct driven by the *neuralized* promoter. In the proximal region of the disc which gives rise to the notum, *scute* is expressed in proneural clusters which can be assigned to individual macrochaetes. Arrows indicate SOPs which have emerged from some of the clusters. In the distal region, one large stripe of *scute* expression coincides in position with the prospective wing margin (wm) and foreshadows the appearance of several rows of microchaetes. (c) Two-step model of SOP specification. During step 1, small groups of contiguous cells (proneural clusters) express a given proneural gene and thereby become committed towards a neural fate. In step 2, lateral inhibition within proneural clusters results in the specification of only one SOP, whereas the remainder of the cells within a proneural cluster become epidermoblasts. (d) Pattern of bristles on the notum of wild-type *Drosophila* (upper panel). Removing *Notch* function at the time interval when lateral inhibition of notum SOPs occurs (8–12 h after puparium formation) causes a strong hyperplasia of bristles. (e) The Notch–Delta signaling pathway. For details see text. Scale bar = 50 μm (b), 10 μm (d). ((a) Adapted from Ferris, G.F., **1965**. External morphology of the adult. In: Demerec, M. et al., 2002) (see **Chapter 1.10**) (**Figure 8b**). Proneural genes are essential for the development of SOPs. In the absence of these genes, SOPs will not form. In *Drosophila*, several different proneural genes have been identified to date. All of them belong to the family of basic helix-loop-helix (bHLH) proteins (see **Chapter 1.8**). Three of them, *achaete* (*ac*), *scute* (*sc*), and *lethal of scute* (*l'sc*) form part of a large gene complex, the Achaete-Scute complex (AS-C), which also encodes other transcription factors involved at later steps of sensillum development. These three genes are expressed in and required for proneural clusters that give rise to mechano-sensory external sensilla and most type II multidendritic neurons. *atonal* (*ato*) determines proneural clusters for chordotonal organs, chemoreceptors, and photoreceptors (Jarman *et al.*, 1993,

1995) (see **Chapter 1.12**), and *amos* (Goulding *et al.*, 2000) is expressed in chemoreceptors and some type II sensilla.

1.11.2.3. Neurogenic Genes and Lateral Inhibition

During a second step, the number of SOPs formed in each proneural cluster is reduced by a mechanism called lateral inhibition (**Figure 8c**). Thus, proneural genes activate a signaling pathway in the cells in which they are expressed, the Notch/Delta (N/Dl) pathway, which inhibits proneural gene expression in all but a few cells (Muskavitch, 1994; Campos-Ortega, 1995; Artavanis-Tsakonas *et al.*, 1999). Genes encoding elements of the lateral inhibition pathway, such as the gene *Notch* that encodes the receptor, *Delta* (encoding the Notch ligand), or *Enhancer of split complex* (*E(spl)*; encoding transcription factors inhibiting proneural genes) are called neurogenic genes, because, in their absence, a large excess of SOPs develops. Thus, in normal development, cells which turn down proneural genes due to N/Dl signaling will join the cells outside the proneural clusters and develop as epidermal cells. If the N/Dl signaling pathway is deficient, all cells of the proneural cluster become SOPs, resulting in many supernumerary sensilla and holes in the epidermis (**Figure 8d**).

As seen in the later section, N/Dl signaling is also a key mechanism distinguishing between the different sensillum cell fates, and the elements of this pathway should therefore be introduced in some detail (**Figure 8e**). Upon binding to a signaling protein (e.g., Delta), the cytoplasmic domain of the Notch receptor is cleaved and translocates to the nucleus where it activates target genes, notably the transcription factors encoded by the Enhancer of split Complex. These proteins promote the development of epidermal cells, as opposed to SOPs, by inhibiting the proneural genes. E(spl) proteins belong to the group of Hairy-related proteins, a distinct subfamily of bHLH proteins that generally operate as DNA-binding transcriptional repressors. They act in opposition to bHLH transcriptional activator proteins (such as the proneural proteins); together, the activator and repressor genes that encode these proteins have co-evolved as a regulatory gene "cassette" involved in many cell fate decisions, including the formation of sensory organs.

The activation of *E(spl)* requires a number of additional nuclear proteins that form a complex with Notch and, in a context-dependent manner, either activate or inhibit Notch function. The DNA-binding transcription factor Suppressor of Hairless (Su(H)) functions as an activator when Notch signaling is active, but can act as a repressor in the absence of signaling. Hairless (H) antagonizes N signaling by inhibiting DNA binding of Su(H) (Lecourtois and Schweisguth, 1997; Artavanis-Tsakonas *et al.*, 1999; Bray and Furriols, 2001).

1.11.2.4. SOP Induction

For a number of sensilla which occur in a tight cluster, such as campaniform sensilla on the appendages or the lateral chordotonal organs of the *Drosophila* embryo, SOPs are determined in a specific sequence, and early SOPs send out signals that induce later ones. The induction of SOPs has been studied for the embryonic chordotonal organ lch5, which comprises five scolopidia aligned in a row. Only the SOPs for three scolopidia express and require the proneural gene *atonal*. The SOPs of the other two scolopidia are induced by the Transforming Growth Factor α(TGFα)-like signaling molecule Spitz (Spi), which activates the MAP kinase (MAPK) signaling pathway (Lage *et al.*, 1997). This signaling pathway mediates a number of inductive events in the developing nervous system of *Drosophila*, notably the specification of photoreceptors and accessory cells in the compound eye.

1.11.2.5. SOP Identity Genes

Although initially indistinguishable, SOPs become different from each other as they undergo mitosis, giving rise to different types of sensilla. This implies that, from an early stage onward, they express determinants responsible for the different SOP fates. First among these determinants are the proneural genes which, after SOPs have become selected from the proneural clusters, are enriched in the SOPs. As described above, the expression of five proneural genes, *ac*, *sc*, *l'sc*, *ato*, and *amo*, accounts for the determination of three fundamentally different classes of sensilla, namely mechanosensory external sensilla, chordotonal organs, and chemosensory external sensilla. Loss of any of these genes causes the corresponding class of sensilla to be absent. In addition to the proneural genes, several transcription factors expressed in SOPs slightly later were identified. Deserving of particular mention among these are *cut* (*ct*) and *pox-neuro* (*poxn*), both encoding proteins containing a homeodomain. *cut* is expressed in SOPs of all external sensilla, *poxn* in SOPs of chemoreceptors and thermo/hygroreceptors (Bodmer *et al.*, 1987; Blochlinger *et al.*, 1990; Dambly-Chaudiere *et al.*, 1992; Vervoort *et al.*, 1995; Awasaki and Kimura, 1997). Loss of *ct* causes the transformation of external sensilla into

chordotonal organs; loss of *poxn* results in a transformation of chemoreceptors into mechanoreceptors. In the case of *ct* it was shown that this gene suppresses the expression of *atonal* in external sensilla, explaining the loss of *ct* function phenotype as the result of an expansion of the *ato* expressing domain. Much remains to be learned about the interplay between proneural and SOP identity genes.

1.11.2.6. Morphogen Gradients and Coordinate Genes

The expression pattern of proneural genes roughly determines the pattern of sensilla on the bodywall of an insect. That leads to the question of how the proneural gene expression pattern itself is controlled. Although our knowledge concerning this issue is still very preliminary, a general mechanism involving morphogen gradients (see also **Chapters 1.8** and **1.9**) and coordinate genes is at the root of the process (**Figure 9**). Morphogens are envisioned as diffusible molecules that are released from one or more discrete sources. As a result, the concentration of these morphogens is high near the source, and decreases with increasing distance from the source (**Figure 9a**).

Morphogens act as signals that control gene expression in a concentration-dependent manner. Thus, cells receiving a high concentration of the morphogen express genes that are different from those expressed by cells encountering a low morphogen concentration. In this manner, the concentration of the morphogen within its dorsal-to-ventral gradient is thought to provide cells in a developmental field with the positional information that directs their differentiation at a given position. Assuming a two-dimensional field, such as the ectodermal domain that will give rise to one segment of the insect body, a minimum of two morphogens would be required to determine the anterior–posterior (ap) and dorsal–ventral (dv) coordinates that constitute the positional information of a given cell (**Figure 9b**).

Morphogens act on patterning by controlling the pattern of expression of a diverse group of genes, which can best be described as coordinate genes. These genes will appear in domains shaped like stripes, oriented either longitudinally (if the corresponding gene responds to the dorsoventral morphogen gradient) or transversally (if it is affected by the anteroposterior gradient). The coordinate genes in turn will control determinants (such as the proneural genes) for specific structures that are destined to develop in the corresponding domains (**Figure 9a**).

The role of morphogens and coordinate genes in the context of sensillum patterning has been studied in most detail in the *Drosophila* embryonic ectoderm and imaginal discs. A molecule fitting the description of a dorsoventral morphogen is Decapentaplegic (Dpp), a member of the TGF family of growth factors, which is expressed at the dorsal margin of the ectoderm (**Figure 9d**). In the imaginal discs, Dpp is expressed at the most proximal parts, which give rise to the dorsal epidermis of the adult body (e.g., the notum in the case of the mesothoracic wing disc; see **Chapter 1.9**). Lowering the Dpp concentration results in the lack of dorsal structures (dorsal sensilla and other epidermal specializations) and the encroachment of ventral structures into dorsal territories (Tomoyasu *et al.*, 1998; deCelis *et al.*, 1999). Two of the coordinate genes dependent on Dpp are *pannier* (*pnr*; a transcription factor of the GATA family), and *iroquois* (*iro*; a homeodomain protein; Gomez-Skarmeta *et al.*, 1996; Leyns *et al.*, 1996; Garcia-Garcia *et al.*, 1999). *Pnr* requires a high Dpp level and is therefore expressed right next to the dorsal midline (**Figure 9e and f**); Iro appears laterally of Pnr (**Figure 9e**). Both Pnr and Iro are required for the upregulation of the proneural gene *sc* in the proneural domains that fall within their respective stripes of expression (**Figure 9i–l**).

Two other secreted signals, Wingless (Wg) and Hedgehog (Hh), play a role in patterning sensilla by affecting proneural gene expression. In the embryo, both are expressed in transverse stripes flanking the segment boundaries, thereby forming gradients along the ap axis (**Figure 9c**). In the wing imaginal disc, Wg is expressed along the margin, and Hh in a longitudinal stripe along the middle of the wing blade. Although the molecular details of how Wg or Hh interact with proneural genes are still unknown, they are both required for the expression of these genes (Phillips and Whittle, 1993; Garcia-Garcia *et al.*, 1999; Phillips *et al.*, 1999). In embryos lacking Wg, proneural genes are not expressed and no sensilla form in any of the trunk segments (**Figure 9h**). Likewise, Wg loss during wing development causes the absence of proneural genes along the wing margin.

1.11.3. Control of SOP Division and Sensillum Cell Fate

1.11.3.1. The Canonical SOP Lineage

Recent studies using high resolution markers were able to visualize division events that had previously been overlooked. These led to the satisfying conclusion that there exist a few, if not only one, fundamental SOP lineages that can account for the different types of sensilla, including external sensilla, chordotonal organs, and type II multidendritic sensilla (Lai and Orgogozo, 2004).

In most cases, all individual cells of a sensillum are born in three consecutive divisions. The SOP,

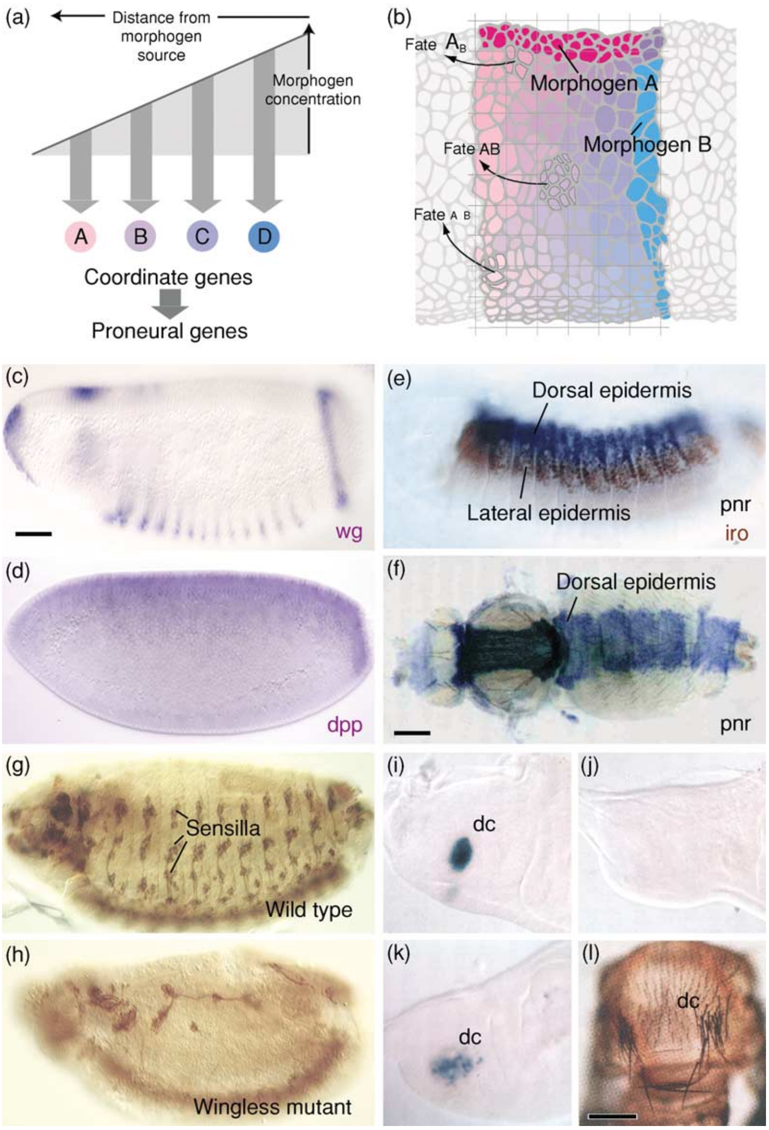

Figure 9 Morphogen gradients control proneural genes via coordinate genes. (a) Schematic diagram illustrating the concept of concentration-dependent activation of coordinate genes by morphogen. (b) Schematic diagram of a developmental field exemplified by a *Drosophila* embryonic segment. Ectoderm cells are indicated by gray outlines. Two morphogens, A (red) and B (blue) are produced along the dorsal and posterior segment boundary, respectively. Their localized secretion causes a graded concentration across the segment. Like a point in a Cartesian coordinate system, each cell in the field is characterized by a certain concentration AB of the two morphogens and adjusts its fate accordingly. (c) Expression of the morphogen gene *wingless* in segmentally reiterated stripes in the early *Drosophila* embryo. (d) Expression of the morphogen gene *dpp* along the dorsal midline of the early *Drosophila* embryo. (e) Expression of the coordinate genes *pannier* (blue) and *iroquois* (brown) in the *Drosophila* embryo. (f) Expression of *pannier* in the dorsal epidermis of the adult fly. (g) Late *Drosophila* wild-type embryo in which sensilla were labeled with the antibody Mab22C10. (h) Late *wingless* mutant embryo. Sensilla are all but absent. also called the primary precusor cell or pI, divides into two pII daughters called pIIa and pIIb (Figure 10a1). PIIa divides once more and gives rise to the outer accessory cells, the tormogen, and trichogen cell for the case of an external sensillum, and the cap cell and attachment cell for the case of a chordotonal organ (Figure 10a4, b and c). PIIb gives rise to the sensory neuron(s) and inner accessory

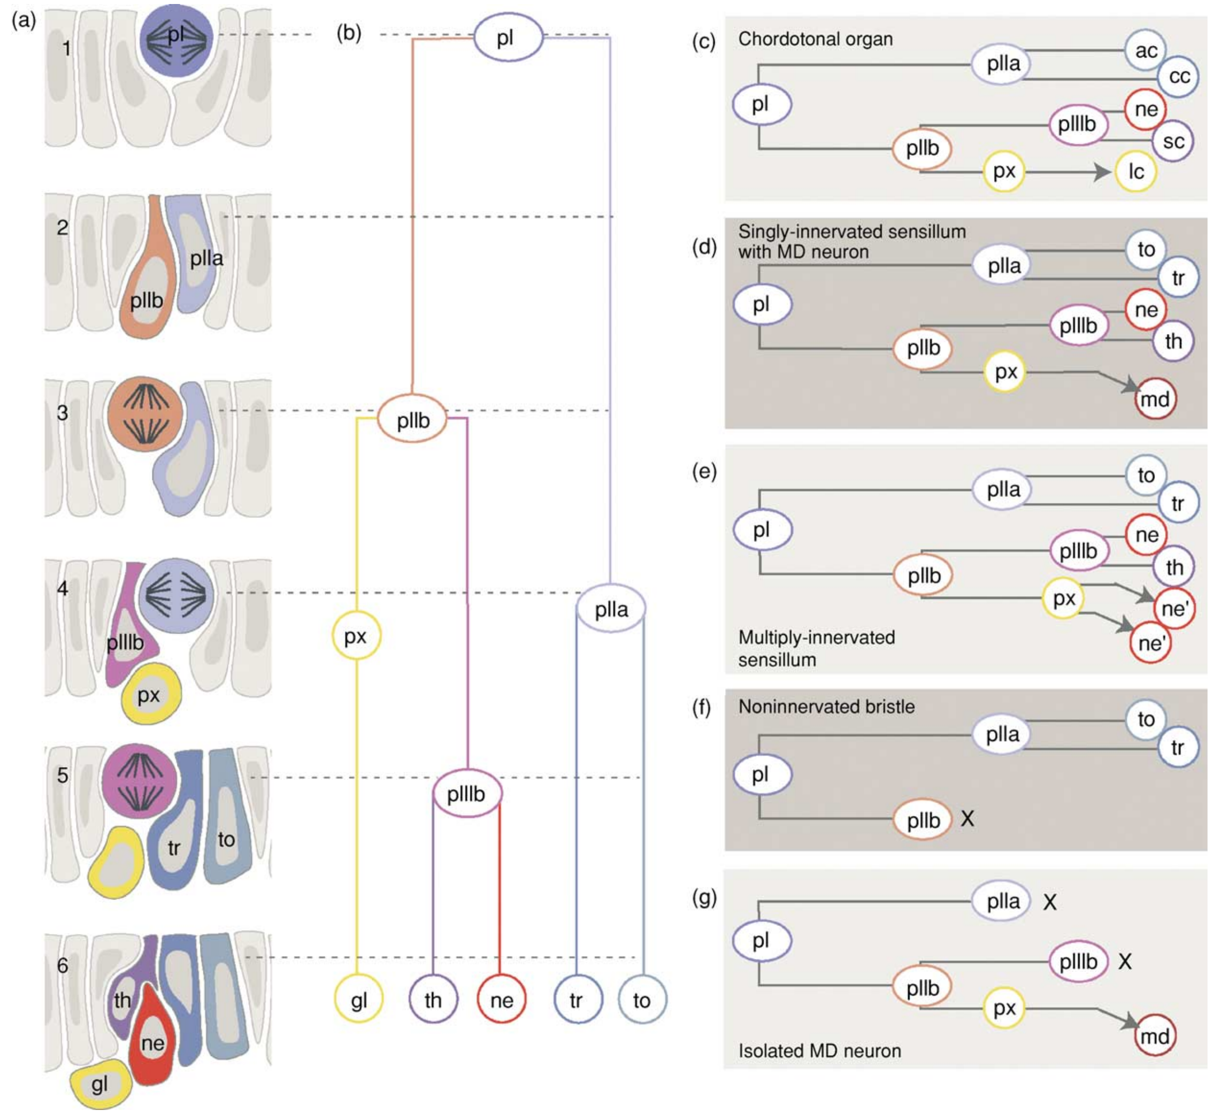

Figure 10 The SOP lineage. (a) Series of schematic sections of the *Drosophila* microchaete SOP. The initial division of this cell (a1) takes place with a horizontal mitotic spindle. The daughter cells resulting from this division are the two secondary precursors, pIIa and pIIb, which lie beside each other in the epithelium of the pupal notum (a2). Subsequently pIIb divides with a vertical spindle (a3), causing one of its daughters, pX, to be located subepidermally (a4), whereas the other daughter, pIIIb, remains within the epithelium. Panel a4 also depicts the horizontal division of pIIa which produces two postmitotic cells, the presumptive tormogen cell (to) and the trichogen cell (tr; a5). PIIIb undergoes its final division with another vertical spindle (a5), forming an epithelial thecogen cell (th) and a subepidermal neuron (ne; a6). (b) Tree diagram of the canonical microchaete SOP lineage. Hatched lines spanning between panels a and b match the division events shown graphically in (a) to the lineage tree shown in (b). (c–g) Lineages of SOPs that produce a variety of different sensilla (indicated at the top or bottom of each panel). Note that all of these lineages represent variations on them represented by the canonical lineage shown in (a) and (b). For details see text. ((a) Adapted from LeBorgne, R., Bellaiche, Y., Schweisguth, F., **2002**. *Drosophila* E-cadherin regulates the orientation of asymmetric cell division in the sensory organ lineage. *Curr. Biol. 12*, 95–104. (c) Adapted from Lai, E.C., Orgogozo, V., **2004**. A hidden program in *Drosophila* peripheral neurogenesis revealed: fundamental principles underlying sensory organ diversity. *Devel. Biol. 269*, 1–17.)

cells in two consecutive divisions. The first division produces precursor pIIIb, which divides into sensory neuron and thecogen cell (external sensilla) or scolopale cell (chordotonal organs), and a postmitotic cell which can adopt a variety of different fates (pX; Figure 10a4 and b). These fates include that of a glial cell (many external sensilla; Figure 10b), ligament cell (many chordotonal organs; Figure 10c), or a multidendritic type II sensory neuron (Figure 10d). In cases of multiply innervated (chemosensory) sensilla, pX undergoes additional rounds of divisions giving rise to the extra neurons (Figure 10e).

Shortly after the SOP has gone through this stereotyped sequence of mitoses, SOPs are located at

characteristic locations relative to the epidermal epithelium. In external sensilla, the tormogen, trichogen, and thecogen cell form an integral part of the epidermis, and only the neuron(s) and glial cell are subepithelial (**Figure 10a6**). In chordotonal organs, all cells are subepidermal; the same is the case for multidendritic neurons.

The cell type-specific location is at least in part the result of the orientation of the mitotic spindle during the SOP division. In external sensilla, division of pI is typically in the plane of the epithelium, so that both pIIa and pIIb remain side by side in the epithelial layer (**Figure 10a1** and **a2**). Similarly, pIIa divides horizontally and forms the two epithelial outer accessory cells (**Figure 10a4** and **a5**). The relative position of the daughter cells resulting from these two divisions is not random. For example, in the michrochaetes of the *Drosophila* thorax, pIIb is always located anterior to pII, and the trichogen cell is anterior to the tormogen cell. The position of these cells seems to play an important role in later sensillum differentiation. Thus, the bristle shafts of microchaetes are all directed posteriorly (**Figure 8d**). Experiments that alter the mitotic spindle of pI and/or pIIa (see below) result in misoriented microchaetes.

Unlike pIIa, which divides horizontally and with a spindle oriented like that one of pI, pIIb typically switches spindle orientation, such that the pX daughter (to become glial cell or multidendritic neuron) is pushed subepidermally, and pIIIb remains intraepithelial (**Figure 10a3**). PIIIb (in those few cases where it has been followed in detail) also seems to divide vertically, with the thecogen cell remaining intraepithelial, and the neuron subepidermal (**Figure 10a5** and **a6**).

Spindle orientation has not been investigated in sufficient detail for chordotonal lineages. It has been reported that for most of the embryonic chordotonal organs in *Drosophila*, the primary pI delaminates and divides in a subepidermal location (Younossi-Hartenstein and Hartenstein, 1997). This would explain the subepidermal location of the accessory cells of a chordotonal organ, whose counterparts in external sensilla form an integral part of the epidermis.

SOP lineage patterns that deviate from the above canonical pattern have been described for some sensilla. For example, olfactory sensilla in numerous insect orders possess three outer accessory cells, whereby the socket is formed by an outer and inner tormogen cell, rather than a single tormogen cell (Keil, 1992). (see also **Chapter 1.12**). In this case it was observed that the outer tormogen cell derives from an additional mitosis which precedes the pI division. In other words, a cell "p0" divides into the outer tormogen cell and a second daughter, which subsequently divides like the classical pI. A similar p0 division, resulting in an outer accessory cell and a pI-like progenitor, was seen in chordotonal organs of *Periplaneta* (Bloechl and Selzer, 1988) and in *Limnophilus* (Roensch, 1954). In evaluating this and numerous other division SOP lineage patterns, it should be borne in mind that, in the absence of injected or molecular markers, the fate of individual cells of the SOP lineage prior to their differentiation is very difficult to follow. Even in *Drosophila*, the pIIb division was overlooked by all authors prior to the studies by Manning and Doe (1999) and Reddy and Rodrigues (1999), even though some limited molecular labeling was available from the outset of such studies. It seems appropriate to feel fairly confident about the canonical lineage for most sensilla in *Drosophila*, but, also, to reinvestigate lineage patterns that have been reported to be different in other systems as molecular markers become available and the need arises.

Apoptosis (see **Chapter 2.5**) plays an essential role in several SOP lineages and reduces the number of cells that make it into the mature sensilla. In the *Drosophila* microchaete lineage, most pX cells undergo programmed cell death (Fichelson and Gho, 2003), and only a few cells survive to form glial cells around the sensory axons. In mature mechanoreceptive external sensilla, trichogen cells are frequently absent; these cells, after having deposited the cuticle-forming bristle shaft, undergo apotosis. Apoptosis also removes a fraction of sensory neurons in multiply chemosensory neurons in the lepidopteran *Pieris* (Lee and Altner, 1985). Apoptosis is also critical in the formation of noninnervated hairs, such as those found along the posterior margin of the fly wing, or scales in lepidopteran wings. These noninnervated epidermal appendages derive from progenitors that divide according to the canonical pattern into a pIIa and pIIb, followed by apoptosis of pIIb (**Figure 10f**). Finally, some of the *Drosophila* larval type II multidendritic neurons develop from SOP lineages in which all but the pX cell are removed by apoptosis (**Figure 10g**; Lai and Orgogozo, 2004).

In the canonical SOP lineage described above, sensilla derive from a single pI that divides into a pIIa and pIIb daughter cell. However, sensilla have been described, where "switching" of pIIa cells and pIIb cells occurs. Cases in point are the dense arrays of sensilla on the *Drosophila* wing margin and antenna (Reddy *et al.*, 1997). Here, SOPs also divide into secondary precursors with the characteristics of pIIa (producing tormogen and trichogen cell) and pIIb (producing neurons and thecogen cell). However, the pIIa of one SOP can join the pIIb of a different (adjacent) SOP to become part of one

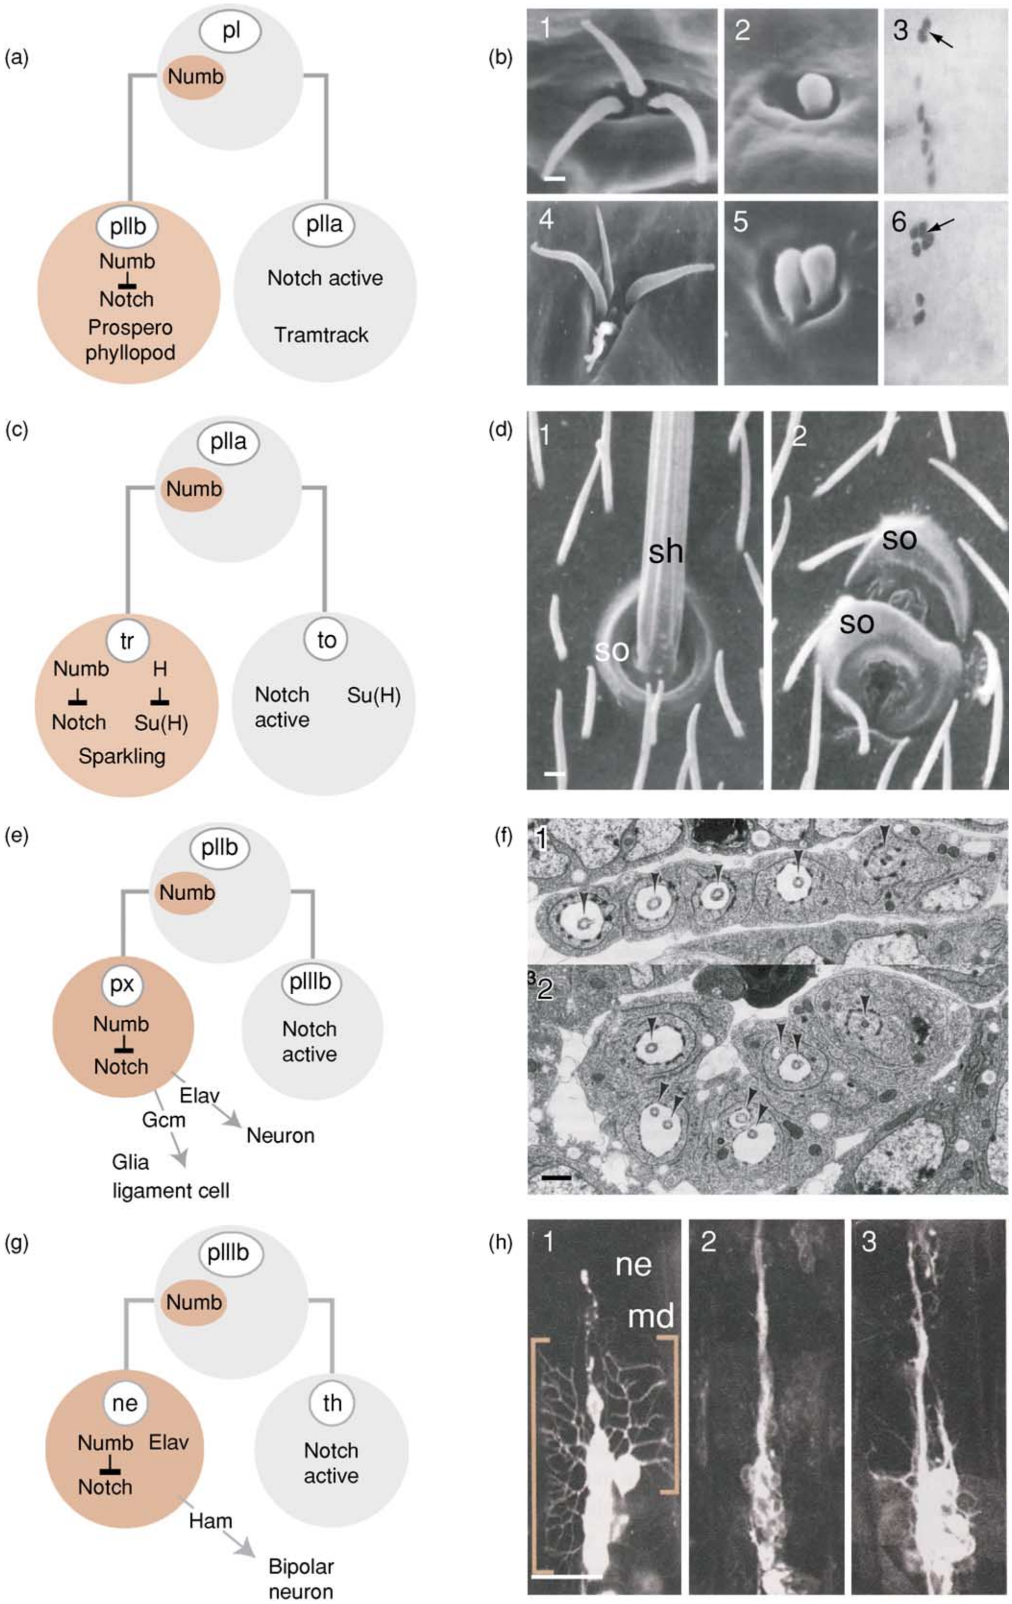

Figure 11 Distribution of fate determinants and Notch signaling in the SOP lineage. (a) During the pI mitosis, Numb, an inhibitor of Notch signaling, is distributed to pIIb. (b) Loss of Numb in pI causes transformation of pIIb into pIIa, with a concomitant doubling of outer accessory cells and absence of neuron/thecogen cell. Examples of this transformation are the Keilin's organ which, in wild type (b1) has three shafts/sockets and, in *numb* mutant (b4), has five to six shafts/sockets. Likewise, duplication of the shaft occurs in the basiconical sensillum vbd (b2): wild type; (b5): *numb* mutant). (b5) shows molecular marker Cut expressed in two outer

individual sensillum. Thus, cell–cell interaction must occur between pII cells, which make sure that one pIIa always becomes conjoined with one pIIb. Observations such as this one support the idea that at an earlier stage in evolution, sensory neurons probably employed signals that recruited neighboring cells into an accessory cell fate (Lai and Orgogozo, 2004; see below).

1.11.3.2. Intrinsic Determinants, the Notch Pathway, and Sensillum Cell Fate

A considerable number of proteins expressed in various parts of the SOP lineage have been identified. Most of these "sensillum cell determinants" have proven essential for the fate of the cell in which they are expressed, in that their absence causes loss or malformation of the corresponding cell. However, little is as yet known about the way in which these intrinsic factors control sensillum cell differentiation. It seems clear that their effect has to be quite indirect in most cases, since the proteins found in specific sensillum cells are also expressed in several other cell types, such as the cells of the compound eye. The other generalization that can be made is that most of the sensillum cell determinants are controlled by the N/Dl signaling pathway, or are themselves part of the mechanism controlling this pathway. This finding underlines the notion that sensillum cell fate determination is the outcome of intricately linked intrinsic control mechanisms and cell–cell signaling (reviews: Posakony, 1994; Cayouette and Raff, 2002; Lai and Orgogozo, 2004; see also **Chapter 1.10**).

1.11.3.2.1. The pI division – pIIa and pIIb Asymmetric expression of sensillum fate determinants originates with the first division of pI into pIIa and pIIb (**Figure 11a**). A crucial factor in generating this asymmetry is the protein Numb. In pI, the Numb protein becomes localized to one side of the cytocortex, so that when this cell divides, only one daughter "inherits" Numb (**Figure 11a**) (Uemura *et al*., 1989; Rhyu *et al*., 1994; Guo *et al*., 1996; Frise *et al*., 1996; **Chapter 1.10**). The cell containing Numb becomes pIIb. The role of Numb in pIIb is to disrupt the N signaling pathway, by preventing N from translocating to the nucleus. Thus, upon activation of the N receptor in both pIIa and pIIb, the signal can get through only in pIIa. If *numb* is deleted, N can act in both pII cells, which changes the fate of pIIb to that of pIIa, and causes a duplication of outer accessory cells and loss of neuron/thecogen cell (**Figure 11b**).

Inhibition of N in pIIb causes several subsequent transcriptional regulators important for the neural fate to be expressed in this cell. Among these is Prospero (Pros), a transcription factor which appears in pIIb and both of its daughters, the neuron and thecogen cell. Subsequently, Prospero is downregulated in the neuron but maintained in the thecogen cell (Manning and Doe, 1999; Reddy and Rodrigues, 1999). Loss of *prospero* causes the same phenotype as that following loss of *numb*, i.e., the conversion of pIIb into pIIa, thus producing two trichogen and two tormogen cells, and no neuron/thecogen cell. Ectopic expression of *pros* (or *numb*) results in the duplication of neuron/thecogen cell, and loss of tormogen/trichogen cell. A second protein with the same distribution and effect as Prospero is Phyllopod (Phyll), a signal transducer in the Ras pathway (Pi *et al*., 2001).

A factor that is activated, rather than inhibited, by the N pathway is Tramtrack (Ttk), a member of the BTB/POZ domain family of transcription factors (Guo *et al*., 1995; Okabe *et al*., 2001; **Figure 11a**). Ttk accumulates in pIIa, and absence of this protein causes the transformation of pIIa into pIIb, with the

accessory cells of the sensillum dc2 (arrow); in *numb* mutant (b6) these cells have increased to four. (c) Following the pIIa mitosis, determination of the trichogen cell (tr) requires Numb, Hairless (H), and the Pax-2 homolog, Sparkling/Shaven. (d) In loss of *hairless* function (d2), the trichogen cell is transformed into a tormogen cell, causing the appearance of a double socket (2xso), instead of a shaft (sh) and socket as in wild type (d1). (e) During the pIIb division, Numb is inherited by pX. This cell can then give rise to a neural or glial/ligament cell, depending on the expression of Elav or Gcm, respectively. (f) Loss of *gcm* causes transformation of ligament cell into supernumerary neuron in *Drosophila* larval chordotonal organs. Wild-type chordotonal organ (f1) posses one dendrite per scolopidium (arrowheads); in many scolopidia of *gcm* mutant embryos (f2) one finds two dendrites (arrowheads). (g) Following pIIIb mitosis, Numb is distributed to the neuron. Realization of the neural fate requires Elav; the distinction between bipolar and multidendritic neuron depends on the expression of the transcription factor Hamlet (Ham). (h) Dorsal sensory neurons in wild-type embryo (h1) represent a mixture of bipolar (ne) and multidendritic (md; brackets) neurons. In embryos overexpressing Ham under the control of different promoters (h2, h3), multidendritic neurons are transformed into bipolar neurons. Scale bar = 1 μm (b, d, f); 10 μm (h). ensuing loss of outer accessory cells and duplication of neurons/thecogen cells.

1.11.3.2.2. The pIIa division – trichogen and tormogen cell Just as in the original pI, pIIa starts out with an activated N signaling pathway (**Figure 11c**). As the division into trichogen and tormogen cell occurs, N becomes attenuated in the tormogen cell. Again, Numb is an essential player in inhibiting N signaling. Numb appears in pIIa shortly before its mitosis and localizes to its anterior pole, whereby it ends up in the trichogen cell. Two nuclear proteins, Hairless (H) and Suppressor of Hairless (Su(H)), which form a complex with the cleaved N fragment when it enters the nucleus and binds to target genes, are also an integral part of the asymmetry generating mechanism (Bang *et al*., 1991, 1995; Bang and Posakony, 1992; Schweisguth and Posakony, 1992, 1994; Bailey and Posakony, 1995; Barolo *et al*., 2000). H, a repressor of N, accumulates in both trichogen and tormogen cells. Su(H) becomes restricted to the tormogen cell. Loss of H results in the transformation of trichogen into tormogen cell ("double-socket"; **Figure 11d**). Overexpression of H, or loss of Su(H) or N, causes the opposite phenotype, a duplication of trichogen cell and loss of socket.

The silencing of *N* in the trichogen cell results in the upregulation of the paired-homeobox (Pax) gene *sparkling/shaven* (*sv*; Kavaler *et al*., 1999). Mutations in this gene have an effect on trichogen cell differentiation. Thus, shafts of hairs and bristles formed by this cell are reduced in length or absent.

As outlined above, it has been suggested that the pIIa cell of chordotonal organs divides into the two accessory cells called cap cell and attachment cell (Lai and Orgogozo, 2004). Although it is tempting to speculate that a N-dependent mechanism operates in this asymmetric division, just as it does in the pIIa of external sensilla, no genetic details are known about the chordotonal pIIa.

1.11.3.2.3. The pIIb division – pIIIb and pX Asymmetric localization of Numb causes the inhibition of N signaling in pX. In some external sensilla, pX differentiates as a glial cell; in other cases, it becomes a multidendritic type II sensory neuron (Brewster and Bodmer, 1995, 1996; Orgogozo *et al*., 2001). Glial development is prompted by the expression of *glial cell missing* (*gcm*), a transcription factor that is also pivotal in the specification of glial cells in the CNS (Jones *et al*., 1995; **Chapter 1.10**; **Figure 11e**). By contrast, multidendritic neuronal development is initiated by the expression of Elav, an RNA-binding protein found in all *Drosophila* neurons. It has been recently speculated that neuronal development constitutes the phylogenetically more ancient pathway of pX (Lai and Orgogozo, 2004). Thus, elimination of *gcm*, in cases where pX expresses a glial fate, causes the transformation of this cell into an Elav-positive neuron. In some chordotonal organs, where pX differentiates into a nonneuronal ligament cell that attaches the neuron to the epidermis, loss of *gcm* also causes transformation of the ligament cell into a (bipolar) neuron (Jones *et al*., 1995; **Figure 10f**). It is noteworthy in this context that some chordotonal organs, notably the auditory Johnston's organ in the fly antenna, possess scolopidia which lack a ligament cell, but are innervated by two bipolar sensory neurons each. It is likely that in these scolopidia, one neuron of each pair develops from the pX cell, while the other neuron is born from the asymmetric division of pIIIb (Lai and Orgogozo, 2004).

It has been shown, for several types of chemosensory external sensilla, that the additional bipolar sensory neurons found in these structures are produced by extra rounds of division of the pX cell. In these cases, the gene *poxn*, which is encountered in the previous section as the sensillum identity gene, is responsible for the stimulation of mitosis in pX.

1.11.3.2.4. The pIIIb division – neuron and thecogen/scolopale cell PIIIb divides into a Numb-positive, N-negative, and Elav positive neuronal precursor, and a Numb-negative, N-positive thecogen cell (Wang *et al*., 1997; **Figure 11g**). Manipulation of the N pathway during this asymmetric division results in the expected cell fate changes, just as in the division of pI, pIIa, and pIIb.

BarH1 and BarH2 represent a complex of two homeobox genes which, in the embryo, are specifically expressed in the neuron and thecogen cell (Higashijima *et al*., 1992). Interestingly, these genes do not seem to be involved in the cells in which they are expressed, but excert a noncell autonomous effect on the outer accessory cells. Thus, loss of BarH1/H2 causes the lengthening of the trichogen process, thereby "transforming" papilla sensilla into trichoid sensilla.

A unique cell fate determining gene called *hamlet* (*ham*) specifies the fate of cells derived from pIIIb in embryonic SOP lineages, giving rise to external sensilla and multidendritic neurons (Moore *et al*., 2002; **Figure 11g**). The most notable phenotype of loss of *ham* consists of an increase in multidendritic neurons at the expense of bipolar neurons innervating external sensilla. Further detailed analysis revealed that the products of pIIIb were a multidendritic neuron with its typical large and branched

dendritic arbor, and a trichogen-like cell. Conversely, expression of *ham* in multidendritic neurons normally derived from pIIIb converted these cells into bipolar neurons (**Figure 11h**).

1.11.3.3. The Control of SOP Mitosis

It has been seen in the previous section that the localization of Numb and its subsequent effect on N signaling is mainly responsible for distributing cell fate to the proper cells of the SOP lineage. How is the asymmetric localization of Numb itself controlled?

At the center of this mechanism is a membrane-associated protein complex which has recently been studied in great detail, because it also controls asymmetric divisions in the stem cells of the CNS (neuroblasts), and because it seems to be highly conserved in all bilaterian animals. This complex, among several other elements, contains the proteins Inscuteable (Insc) and Bazooka (Baz; **Figure 12a**; Campos-Ortega, 1997; Wodarz *et al*., 1999; Jan and Jan, 2001; Knoblich, 2001; Chia and Yang, 2002; Lai and Orgogozo, 2004; see **Chapter 1.10**). Located apically in the neuroblasts, as well as the neurectoderm from which neuroblasts delaminate, the Insc complex anchors the centrioles in a vertical orientation, which results in a vertical mitotic spindle. Along with spindle orientation, the basal localization of Numb also depends on the Insc complex. The apically localized Insc complex also controls the vertical spindle and basal localization of Numb in pIIb and pIIIb of the external sensillum SOP lineage (**Figure 12d**), both of which are intra-epithelial cells, which as seen above, give off one daughter basally.

The regulation of the mitotic spindle and Numb localization in pI, which divides horizontally in the plane of the epithelium, requires elements of the Insc complex, in addition to other factors (**Figure 12b**; Orgogozo *et al*., 2001; Roegiers *et al*., 2001). As in neuroblasts and pIIb/IIIB, the asymmetry in Numb

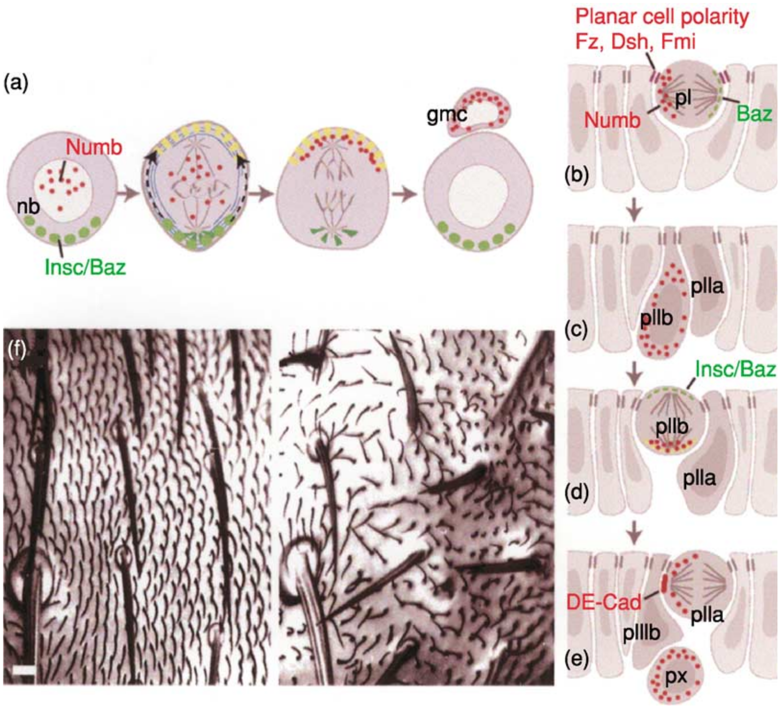

Figure 12 Control of spindle orientation during SOP division. (a) Schematic diagram of neuroblast division. The Inscuteable/Bazooka (Insc/Baz) protein complex is located apically in dividing neuroblasts (nb) and anchors the mitotic spindle (sp) in a vertical position. The same complex, in conjunction with the basally concentrated protein Miranda (yellow), is responsible for asymmetric localization of Numb at the basal side of the neuroblast. After neuroblast division (right panel), Numb becomes localized exclusively in one of the daughter cells, the ganglion mother cell (gmc). (b–e) Schematic drawings of dividing microchaete SOP (see **Figure 10**). Spindle orientation and Numb localization in pI (b, c) is controlled by the Inscuteable complex and the planar cell polarity pathway. Mutations for any member of this pathway (Fz, Dsh, Fmi) result in randomized mitotic spindle orientations, followed by abnormally oriented microchaetes. This condition is illustrated in panel f, where the left half shows wild-type microchaete pattern, and the right half demonstrates the bristle pattern in a mutation of *frizzled*. (d) Vertical spindle orientation in dividing pIIb is controlled by the Insc/Baz complex. (e) Asymmetric division of pIIa does not depend on Insc/Baz, but on the cell adhesion molecule DE-Cadherin (DE-Cad). At most stages, this protein is localized around the apical pole of epithelial cells. At a later stage, when pIIa divides, a discrete spot of DE-Cad appears at a more basal position. Scale bar = 5 µm. ((f): Reprinted with permission from Tree, D.R., Ma, D., Axelrod, J.D., **2002**. A three-tiered mechanism for regulation of planar cell polarity. *Semin. Cell Devel. Biol. 13*, 217–224; © Elsevier.)

localization (accumulated anteriorly in pI) depends on Baz. Eliminating this protein causes randomized spindles and Numb accumulation.

It could recently be demonstrated that molecules that form part of the so-called planar cell polarity (PCP) pathway also play a role in orienting the mitosis of pI of *Drosophila* thoracic microchaetes (**Figure 12b**; Adler and Taylor, 2001; Tree *et al.*, 2002). The PCP pathway involves the membrane receptor Frizzled (Fz) and the signal transducer Dishevelled (Dsh), which is localized to the zonula adherens and becomes hyperphosphorylated as a result of binding to Fz. Other molecules, including the cadherin Flamingo (Fmi), play a role in the proper localization of the Fz/Dsh complex in the membrane (Lu *et al.*, 1999), and effectors downstream of this complex include the *Drosophila* rhoA GTPase (DrhoA), which could directly act on the actin cytoskeleton and thereby exert an effect on cell shape and cell orientation. The PCP pathway controls the orientation of epidermal hairs (trichomes) and directed cell movement, for example, in *Drosophila* compound eye development and vertebrate gastrulation. Impairment of this pathway also causes randomization of the mitotic spindle in pI, followed by abnormal orientation of the microchaete bristles (**Figure 12f**).

In pIIa, the progenitor of the trichogen and tormogen cell, spindle orientation and Numb localization involve a mechanism that does not require the Insc complex. PIIa divides horizontally, and the orientation of the spindle matches that of its mother cell pI, i.e., it is aligned along the ap axis. Even if the pI spindle is randomized (by interference with Insc or Baz), the pIIa spindle lines up with the previous pI spindle. The main factor that has been identified so far in controlling the pIIa spindle is the adhesion molecule *Drosophila* E-Cadherin (DE-Cad; LeBorgne *et al.*, 2002). DE-Cad is concentrated in the zonula adherens of epithelial cells, including pI, pIIa, and pIIb. In pII, it becomes localized in an asymmetric fashion, in that a "patch" of high DE-Cad concentration accumulates at the pIIa/pIIb interface (**Figure 12e**). The asymmetric DE-Cad expression is crucial for pIIa division. Reducing DE-Cad function prior to pIIa division randomizes the mitotic spindle and leads to mislocalization of Numb.

1.11.4. Sensillum Morphogenesis and Differentiation

1.11.4.1. Formation of External Sensilla

Following the division of the SOP of an external sensillum, the presumptive outer accessory cells and thecogen cell form integral parts of the

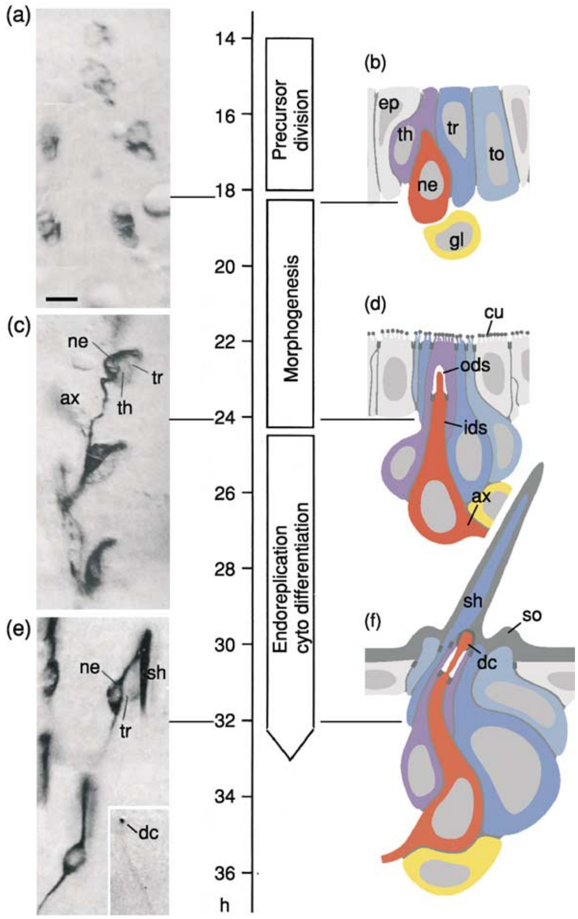

Figure 13 Morphogenesis of external sensilla. Left panels (a, c, e) show photographs of *Drosophila* notum microchaetes, labeled with the antibody Mab22C10, which stains sensory neurons and some of the accessory cells, at three different stages of pupal development. The time line in the center of the figure indicates hours after puparium formation, and provides the time frame for the three major phases of microchaete development (SOP proliferation, sensillum morphogenesis, sensillum differentiation). The right panels (b, d, f) show schematic sections of developing microchaete at stages corresponding to those illustrated by the photographs at the left. (a, b) Shortly after SOP division, accessory cells (to, tormogen cell; tr, trichogen cell, th, thecogen cell) lie in the plane of the epidermal epithelium (ep); neuron (ne) and glial cell (gl) are subepidermal. The 22C10 antibody labels triplets of cells, which correspond to the neuron, thecogen, and trichogen cell. (c, d) During sensillum morphogenesis, the accessory cells form concentric sheaths around the extending sensory dendrite (ids, inner dendritic segment; ods, outer dendritic segment), whilst their cell bodies shift basally. Neurons grow out axons (ax). (e, f) Neuron and accessory cell differentiation. Both trichogen cell and tormogen cell undergo several rounds of endoreplication, resulting in an increase of the size of these cells. At the same time, the shaft (sh) and socket (so) form as apical extensions of the trichogen and tormogen cell, respectively. The dendritic cap (dc) is secreted by the thecogen cell around the tip of the dendrite. Scale bar = 5 μm (a, c, e). ((a, c, e) From Hartenstein, V., Posakony, J.W., **1989**. The development of adult sensilla on the wing and notum of *Drosophila melanogaster*. *Development 107*, 389–405.)

epidermis, while the precursor of the sensory neuron(s) and the pX cell (which will become either glia or neuron, or undergoes apoptosis) are subepidermal (Figure 13b and c). Subsequently these cells undergo a series of morphogenetic changes in shape and position, which leads up to the architecture of the mature sensillum. Sensillum morphogenesis has been described at the ultrastructural level in several insect groups (Blattodea: Seidl and Altner, 1990; Orthoptera: Ameismeier, 1987; Gnatzy,

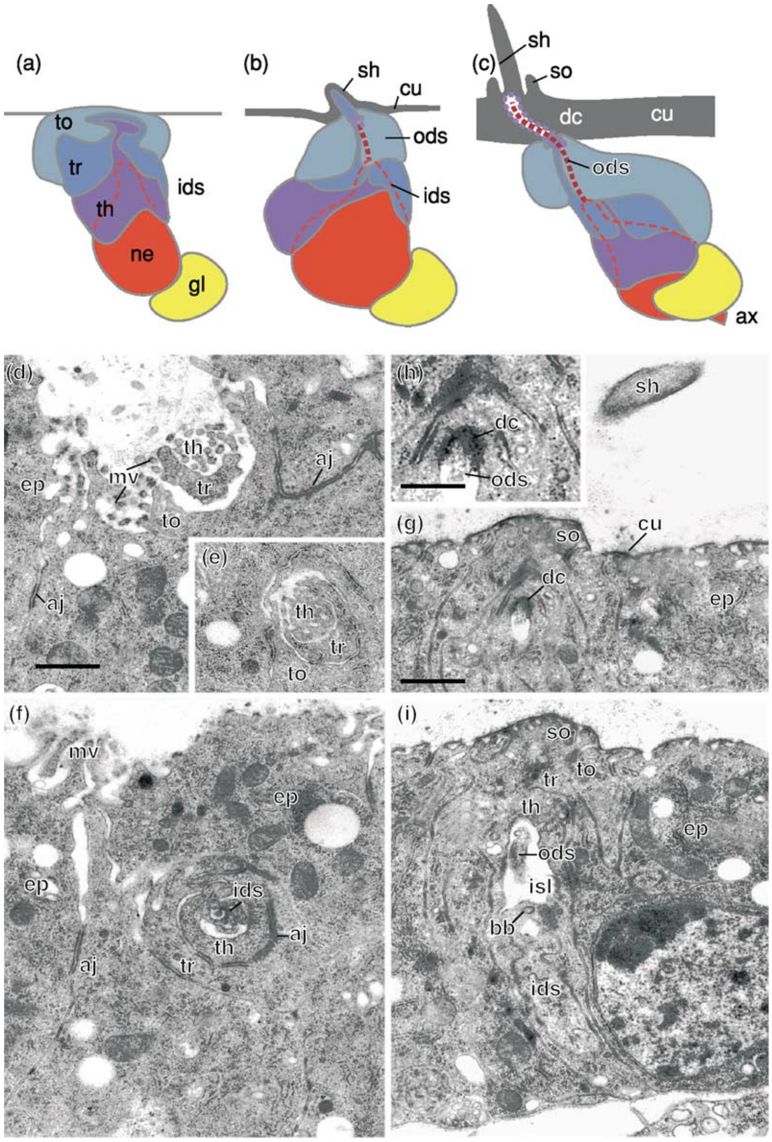

Figure 14 Morphogenesis of external sensilla. (a–c): Semi-schematic drawings of a *Drosophila* trichoid sensillum at embryonic stage 13 (50% of development; (a)), 15 (60% of development; (b)), and 16 (70% of development; (c)), showing sensillum cells (gl, glial cell; ne, neuron; th, thecogen cell; to, tormogen cell; tr, trichogen cell) in different colors. (d–f) TEMs of transverse sections of nascent trichoid sensillum at embryonic stage 13. Sections correspond to different levels along the apico-basal axis of the sensillum, with d showing the most apical level. Note the concentric arrangement of the thecogen cell (th), trichogen cell (tr), and tormogen cell (to) at apical levels (d, e). Microvilli (mv) and conspicuous adherens junctions (aj) characterize the sub-apical membrane of accessory cells and surrounding epidermal cells (ep). The sensory neuron has started to form inner dendritic segment (ids in (f)) which pushes into the thecogen cell from below, but does not yet reach the apical surface of the embryo (note the absence of dendrite in planes shown in (d) and (e)). (g–i) Near longitudinal sections of trichoid sensillum at embryonic stage 16. The sensory dendrite has lengthened and forms a ciliary outer segment (ods) apically. The dendritic cap (dc) is formed between the thecogen cell and the tip of the dendrite (g); (h) shows a magnified view of tip of dendrite with dendritic cap). The tormogen and trichogen cell have formed a sensillum socket (so) and shaft (sh), respectively. Cuticle (cu) is deposited around the socket and shaft, and at the tips of microvilli protruding from epidermal cells (ep). Scalebar = 0.5 μm (d–f, h); 1 μm (g, i). ((a–c) Adapted from Hartenstein, V., **1988**. Development of the *Drosophila* larval sensory organs: spatiotemporal pattern of sensory neurones, peripheral axonal pathways, and sensilla differentiation. *Development 102*, 869–886.)

1978, 1980; Edwards and Chen, 1979; Schmidt and Berg, 1994; Coleoptera: Ernst, 1972; Lepidoptera: Keil, 1992; Hymenoptera: Schmidt and Kuhbandner, 1983; Martini, 1986; Diptera: Hansen and Hansen-Delkeskamp, 1983; Kuhbandner, 1984; 1985; De Kramer and Van der Molen, 1984; Hartenstein, 1988; Hartenstein and Posakony, 1989).

1.11.4.1.1. Formation of the inner dendritic segment and dendritic sheath The first phase in sensillum morphogenesis is embedded in more generalized morphogenetic movements that shape the epidermis surrounding the sensillum. Thus, during a time interval that precedes the deposition of cuticle, epidermal cells, and accessory cells of external sensilla form horizontal, sleeve-like processes that, to a variable extent, insert in between and wrap around neighboring cells. Whereas these processes are transient in regular epidermal cells, they remain in place in the case of trichogen and tormogen cells, resulting in the mesaxonal sheaths formed by these cells around the thecogen cell (**Figures 13d** and **14a, d**). During the same time period, the sensory neuron forms the inner dendritic segment at its apical pole (**Figures 13c, d** and **14b, f**). While pushing upward, the dendrite pierces the cytoplasm of the thecogen cell from a basal to apical direction. This movement results in the cylindrical dendritic sheath formed by the thecogen cell around the dendrite (**Figure 14f**).

Formation of the trichogen and tormogen mesaxon around the thecogen cell follows an apical to basal gradient. Thus, at an early stage of sensillum morphogenesis, a complete mesaxon is only present at the apical level of the zonula adherens (**Figure 14a**); further basally, the tormogen and trichogen sheaths are only partial. Toward the later stages, the width of the mesaxons increases, until most of the length of the dendrite is enclosed by these sheaths (**Figure 14b** and **c**).

The lengthening of the dendrite, and concomitant widening of the accessory sheaths surrounding it, is paralleled by a basal shift of the cell bodies of all sensillum cells. In most mature sensilla, the cell bodies of neuron and thecogen cells are beneath the level of the basal surface of the epidermis, and can be even removed for some distance in the horizontal plane, from the location where the dendrite and its sheath are inserted in the epidermis (**Figure 13e** and **f**). The cell bodies of the tormogen and trichogen cells also shift below the level of the surrounding epidermis (**Figures 13d, f** and **14a–c, i**).

1.11.4.1.2. Elaboration of the apical sensillum apparatus This second phase in morphogenesis is unique to sensillum cells. Thus, whereas surrounding epidermal cells maintain a flat apical membrane that starts to secrete cuticle, the sensory dendrite and its surrounding accessory cell processes grow apically (**Figures 13e, f** and **14b, c, g**). The trichogen cell forms the sensillum shaft that differs in shape and length depending on the type of sensillum (e.g., basiconcal, campaniform, or trichoid sensilla). Apically directed growth of the tormogen cell produces the socket of the sensillum. As the shaft and socket processes approach their mature length, they start to secrete cuticle.

At the same time as the shaft and socket of the sensillum are formed, the sensory neuron extends the outer dendritic segment, which constitutes a modified cilium (**Figures 13f** and **14c, g–i**). The basal body, derived from the centriole that had organized the mitotic spindle of the SOPs, acts as the nucleation center for the array of microtubules forming the axoneme of the cilium. Interestingly, the cilium does not start its outgrowth from the apical membrane of the sensory neuron. Instead, the basal body sinks several microns deep beneath the membrane. A small membraneous vesicle forms above the basal body, and the nascent cilium pushes into the lumen of the vesicle. Subsequently, the vesicle shifts apically and fuses with the apical cell membrane, thereby moving the base of the cilium into the apical membrane. The same mechanism of ciliogenesis is typical for ciliated cells in vertebrates (Keil and Steinbrecht, 1997).

As the outer dendritic segment of the sensory neuron elongates beyond the apical surface of the thecogen cell, it protrudes into the interior of the trichogen shaft. In the case of the many chemosensory sensilla, the dendrite(s) reach all the way to the tip of the shaft; in mechanoreceptors, the dendritic tips terminate at a more basal level (see **Figure 2b** and **c**). The dendritic tip of many mechanosensitive sensilla ends in a characteristic thickening, the tubular body. Like the outer dendritic segment as a whole, the tubular body is filled with microtubules which, in conjunction with the membrane of the tubular body, are the pivotal elements in mechanotransduction.

At the time when cuticle is deposited around the socket and shaft processes of the outer accessory cells, the thecogen cell secretes a dense extracellular material, the dendritic cap (**Figures 13e** and **14g, h**). The dendritic cap forms the "glue" that connects the dendrite to the cuticle of the sensillum shaft; as discussed below, mutations in which this connection is severed result in failure of mechanotransduction.

During molting, the apical processes of the trichogen and tormogen cell retract and grow out anew before the next cuticle layer is deposited. At the

same time, the outer dendritic segments, surrounded by the thecogen sheath, remain at their full length. They can now be seen to protrude beyond the level of the epidermis, leaving the enclosing outer accessory cells through a pore called the molting pore (Gnatzy, 1978). After shaft and socket have reformed, the dendrite is again taken into the interior of these processes.

1.11.4.1.3. Axonogenesis and glial sheath The basal membrane of the sensory neuron lengthens to protrude as the axon. The axon, tipped by a growth cone, extends towards the CNS, typically using the basement membrane underlying the epidermis or surrounding nearby muscles as a substrate to grow on. Sensory axons become surrounded by a perineural glial sheath. Close to the sensory cell body, this sheath is elaborated by the glial cell derived from pX (**Figure 14c**). At more proximal levels, additional glial cells (peripheral glia), unrelated to the SOP lineages, surround sensory nerves. The sheath formed by the pX glial cell occasionally enwraps the sensory cell body as well, such as in the case of the *Drosophila* embryonic basiconical sensilla (Hartenstein, 1988). In most sensilla, the sensory cell body lacks a glial sheath.

1.11.4.1.4. Molecular aspects of bristle shaft differentiation Very little is known about the molecular mechanisms underlying the complex series of early morphogenetic processes that shape the outer accessory cells. It is reasonable to assume that finely tuned changes in adhesion molecule expression and/or distribution account for the gradual formation of the mesaxonal sheath processes produced by the trichogen and tormogen cell; however, the genetic analysis of representatives of the well known classes of adhesion molecules, such as the cadherins, which have been identified to date, has not yet produced any phenotype that would shed light on mesaxon formation and early accessory cell morphogenesis in general. The picture becomes clearer at later stages, when accessory cells form their apical processes, i.e., the sensillum socket and shaft. These events are driven by a dynamic rearrangement of microfilaments and microtubules. Our understanding of this process, which in many respects may serve as a model system for cell elongation in general, has recently improved with the molecular-genetic analysis of *Drosophila* thoracic microchaetes (Tilney *et al*., 1995, 1996, 2000a, 2000b).

The trichogen cell of microchaetes starts forming an apical shaft at around 32 h of pupal development (**Figure 13e**). Shortly after their appearance, shafts reach their final diameter of approximately 4 µm; from then onward, they grow over a time period of 15 h to a final length of about 70 µm. Mature microchaetes are roughly cone-shaped and have a rifled surface (**Figure 15c**). Rifles are caused by 7–11 tight bundles of microfilaments arranged at regular intervals around the periphery of the shaft (**Figure 15a**). These bundles co-vary in thickness with the diameter of the shaft; near the base of the microchaete, bundles are thicker (and contain more microfilaments) than near the tip (**Figure 15d**). Microtubules, rather than forming bundles, are evenly distributed throughout the cytoplasm of the microchaete shaft (**Figure 15a**). Applying drugs that specifically disrupt actin and tubulin turnover to organ cultures of developing microchaetes (Turner and Adler, 1998; Tilney *et al*., 2000b) showed that actin polymerization is essential for bristle elongation, but that microtubules play little role in this process.

Microchaete growth occurs preferentially at the tip by directed polymerization of actin (**Figure 15d**, phase 1). Soon after their formation, microfilaments are tied together into bundles. Following an initial phase of thin, loosely-packed bundles (seen near the tip of the bristle; phase 2 in **Figure 15d**) microfilaments are forced into a maximally cross-linked, hexagonal array, found at more proximal levels of the bristle (**Figure 15d**, phase 3; see high magnification of microfilament bundle in **Figure 15b**). Two different actin binding proteins, Forked (F) and Singed (Sn) (the latter constituting the *Drosophila* homolog of the Fascin protein that is crucial for microfilament bundling in vertebrate cells), are responsible for these two steps in bundling the microfilaments of the microchaete. Loss of either of these proteins causes stunted bristle growth, as well as irregular shapes and branching of the bristle (**Figure 15g and j**). Forked protein is localized at the tip of the growing bristle, where the loose bundling of freshly polymerized actin takes place. In mutations of *forked,* the number of microfilaments that are recruited into the bundles is drastically reduced, resulting in thin bundles; alternatively, the cross-linking step is normal, so that filaments are tightly packed and regularly spaced (**Figure 15f**). Singed is found along the length of the bristle, supporting the notion that this protein is incorporated into the bundles as they mature, which causes the transition from the initial loose packing of filaments into the hexagonal arrays. Bristles of *singed* mutants have reduced microfilaments with loosely packed, irregularly spaced filaments (**Figure 15i**).

Besides the cross-linking proteins Singed and Forked, numerous other proteins, known to play a role in controlling microfilament polymerization

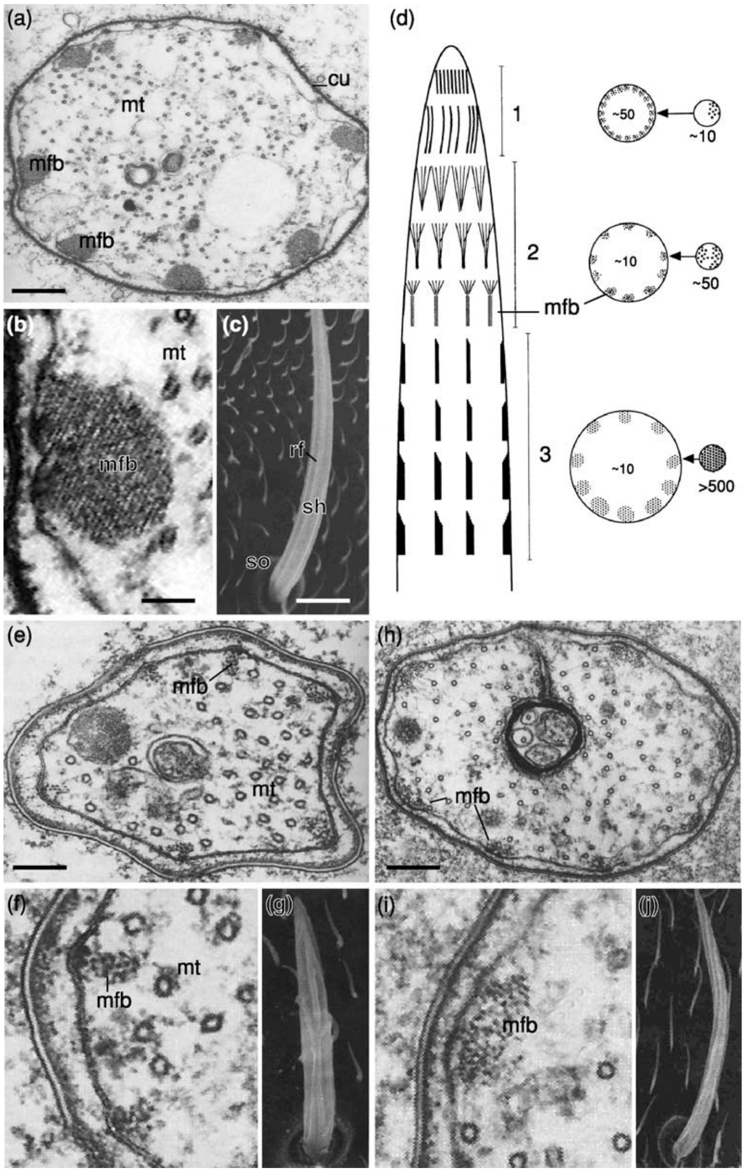

Figure 15 Sensillum differentiation: elongation of the sensillum shaft. (a–c) TEMs (a, b) and SEM of *Drosophila* thoracic macrochaete. Cross-section of the macrochaete shaft (a) shows regularly spaced longitudinal bundles of microfilaments (mfb) and scattered microtubules (mt). (b) Shows magnified view of microfilament bundle, illustrating the ''crystalline pattern'' of hexagonally packed microfilaments. Microfilament bundles impress rifles (rf) on cuticular surface (cu) of macrochaete (a, c). (d) Schematic longitudinal section (left of panel) and consecutive cross-sections (right) of macrochaete shaft. Phases 1 (bristle tip) to 3 (bristle base) correspond to steps in microfilament bundle assembly. During phase 1 microfilaments associate into approximately 50 thin, loosely packed bundles of about 10 fibres each. In phase 2 these bundles coalesce into fewer, thicker bundles. These early phases depend on the Forked protein, which is expressed along the entire length of the bristle. During phase 3, bundles grow in thickness and microfilaments become cross-linked into hexagonal arrays. The fascin homolog Singed, expressed only at the bristle base, is responsible for the cross-linking. (e–g) TEMs and SEM of macrochaete in a *forked* mutant. Note the smaller size of bundles (e) and abnormal bristle morphology (g). Althoughy strongly reduced in size, microfilament bundles still consist of hexagonal arrays of microfilaments (f). (h–j) TEMs and SEM of macrochaete in a *singed* mutant. As in *forked*, microfilament bundles are reduced in size (h), causing abnormal bristle morphology (j); in addition, microfilaments are randomly spaced within bundles (i). Scalebar = 0.5 mm (a, h); 0.1 μm (b, f, i); 10 μm (c, g, j); 0.3 μm (e). ((a–c), (e–j): Reproduced from Tilney *et al.* 1995 by copyright permission of The Rockefeller University Press. (d): Reproduced from Tilney *et al.* 2000a by copyright permission of The Rockefeller University Press.)

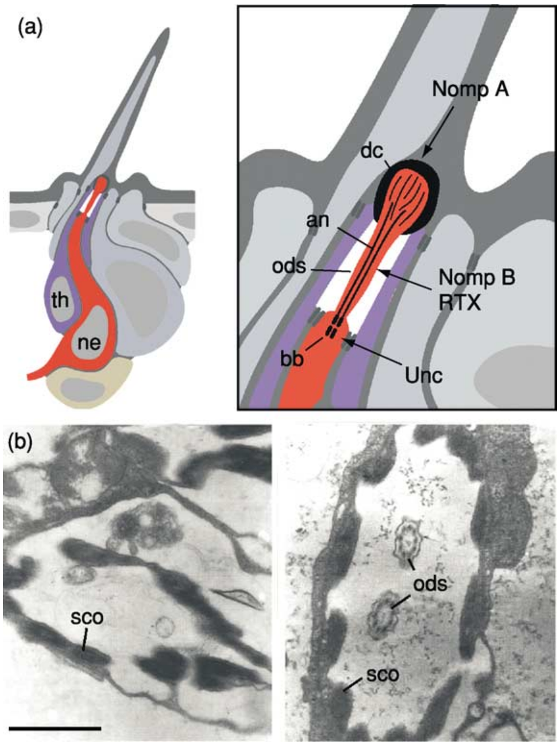

Figure 16 Differentiation of the outer dendritic segment and dendritic cap. (a) Schematic drawing of a mechanosensory sensillum, showing the outer dendritic segment (ods) and related structures (bb, basal body; an, axoneme; dc, dendritic cap). Four proteins involved in sensory dendrite formation (NompA, NompB, RFX, Unc) and their supposed point of action are indicated. (b) TEMs of cross-sections of scolopidia of Johnston's organ of *Drosophila* wild type (right panel) and a *rfx* mutant (left panel). The wild-type scolopale (sco) surrounds two dendrites (ods); no dendrites are detectable in the mutant scolopale. Scale bar = 0.5 μm. ((b): Reproduced with permission from Dubruille, R., Laurencon, A., Vandaele, C., Shishido, E., Coulon-Bublex, M., *et al.*, **2002**. *Drosophila* regulatory factor X is necessary for ciliated sensory neuron differentiation. *Development 129*, 5487–5498; © The Company of Biologists Ltd.)

and bundling, were identified as factors in microchaete growth. Notable among these are Crinkled (Ck), the *Drosophila* homolog of myosin VIIa, and members of the short GTPases (Dcdc42 and DRho; Eaton *et al.*, 1996).

1.11.4.1.5. Factors controlling sensory dendrites and dendritic sheaths Genetic screens for loss of sensory function have led to the isolation of genes important for the development and physiology of sensory neurons. To date, two aspects of sensory neuronal development have been addressed: the outgrowth of the cilium-like outer dendritic segment, and the connection of the dendritic tip to the dendritic cap formed by the thecogen cell (**Figure 16**).

Formation of the outer dendritic segment is driven by the elongation of the axoneme, the circular array of microtubules extending along the ciliary center. Axoneme elongation has been investigated in more detail in other organisms, such as the alga *Chlamydomonas* (Rosenbaum and Witman, 2002) and the nematode *Caenorhabditis elegans* (Swoboda *et al.*, 2000). These studies showed that axoneme formation requires a complex (Intra Flagellar Transport or IFT complex) of several microtubule-binding proteins that are transported along the axoneme. The *Drosophila* gene *no-mechanoreceptor-potential B* (*nompB*) has been suggested to encode one of these transported ciliary proteins (Caldwell and Eberl, 2002; **Figure 16a**). Mutants in *nompB* have shortened sensory cilia in external sensilla and chordotonal organs. Another gene discovered in the systematic screen for mutations deficient in mechanoreception, *uncoordinated* (*unc*), has been suggested to be involved in the formation of the basal body that organizes the outgrowth of the ciliary axoneme (Baker *et al.*, 2001; Caldwell and Eberl, 2002).

The expression of the IFT complex is under the control of a transcription factor of the Regulatory Factor X (RFX) family. *Drosophila rfx* has been recently identified (Dubruille *et al.*, 2002); it is expressed and required for sensory neuronal differentiation and function. Loss of *rfx* results in missing or shortened outer dendritic segments in all bipolar (type I) sensory dendrites, including those of external sensilla and chordotonal organs (**Figure 16a and b**). This developmental defect leads to loss of excitability of the sensory neurons by their appropriate stimuli.

Besides proteins involved in ciliary growth, proteins linking the cilium to the dendritic cap, which is produced by the thecogen cell, have been identified. Mutations in genes encoding such proteins also lead to loss of sensory function, supporting the notion that the tight connection between the dendrite and the dendritic cap is crucial for eliciting a receptor potential in the sensory neuron (Caldwell and Eberl, 2002). One protein required for the dendrite-to-dendritic cap linkage is NompA, a transmembrane protein produced in the thecogen cell and targeted to the dendritic cap. Mutations in the *nompA* gene cause gaps in the dendritic cap around many dendrites (**Figure 16a**; Chung *et al.*, 2001).

1.11.4.2. Chordotonal Organs

1.11.4.2.1. Formation of the *Drosophila* embryonic chordotonal organs The development of chordotonal organs has been analyzed at the ultrastructural level in *Periplaneta* (Bloechl and Selzer, 1988) and *Drosophila* (Hartenstein, 1988). In *Drosophila*,

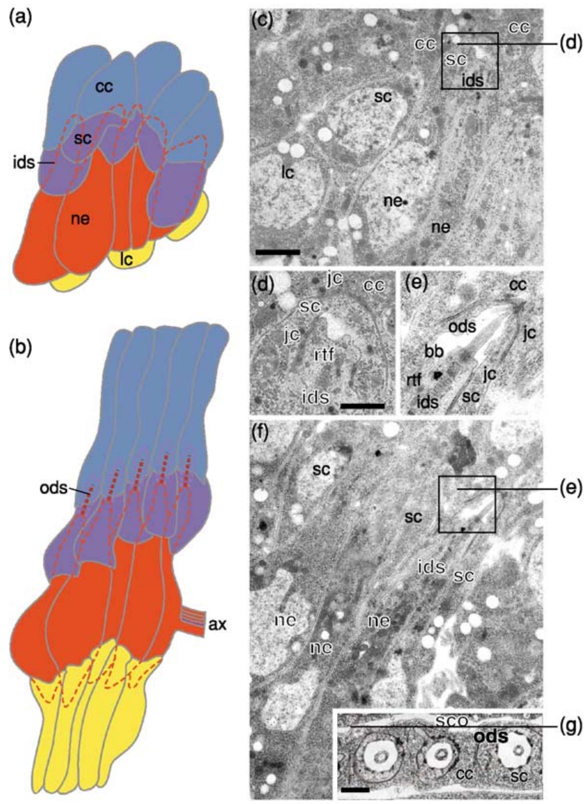

Figure 17 Morphogenesis of chordotonal organs. (a, b) Schematic drawings of a *Drosophila* lateral pentascolopidial organ (lch5) at embryonic stage 13 (a) and 16 (b), showing sensillum cells (lc, ligament cell; ne, neuron; sc, scolopale cell; cc, cap cell) in different colors. (c, d) TEMs of longitudinal section of nascent chordotonal organ at embryonic stage 13. Neurons (ne) are located basally (bottom of panel) and start growing out inner dendritic segments (ids) which push into the apically adjacent scolopale cells (sc). Magnified view of this region in (d) shows rootlet filament (rtf) in inner dendritic segment and junctional complexes (jc) between dendrite, scolopale cell, and cap cell. (e, f) Longitudinal section of the developing chordotonal organ at stage 15 of embryonic development. The main changes from the previous stage are the lengthening of the inner dendritic segment and the appearance of a short ciliary outer segment (ods) emanating from a basal body (bb). (g) Transverse section of a stage 16 chordotonal organ, showing the formation of scolopidial rods (sco) in the cytoplasm of scolopale cells. Scale bar = 0.5 µm (c, f, g); 0.2 µm (d, e). ((a, b) Adapted from Hartenstein, V., **1988**. Development of the *Drosophila* larval sensory organs: spatiotemporal pattern of sensory neurones, peripheral axonal pathways, and sensilla differentiation. *Development 102*, 869–886. (g): Reprinted with permission from Jones *et al.* 1995; © Elsevier.)

following SOP division, presumptive chordotonal cells are all located subepidermally and become arranged in the form of columns, each column representing one scolopidium (Figure 17a). In the case of the embryonic lateral chordotonal organ lch5, presumptive attachment cells are located most dorsally, attached to the basal membrane of the epidermis. Attachment cells are followed by cap cells, scolopale cells, neurons, and ligament cells (called soma sheath cells in Hartenstein (1988)). As morphogenesis begins, sensory neurons form dendrites that extend dorsally into the adjacent scolopale cells (Figure 17a, c and d). This event resembles, in many ways, the behavior of external sensillum neurons whose dendrites "pierce" the apically adjacent thecogen cell (the homolog of the scolopale cell; see above). However, dendrites of chordotonal sensory neurons do not protrude beyond the scolopale cell; rather, they remain "buried" in a conical cavity surrounded by the scolopale cell (Figure 17b, e, f). The scolopale cell itself also lengthens in the vertical axis and pushes into the cap cell. Prominent adherens junctions and septate junctions strengthening the intercellular adhesion form in the vaulted clefts in between the cap cell and scolopale cell, and scolopale cell and dendrite (Figure 17d and e).

Two cells, the attachment cell (apically) and the ligament cell (basally) (see Figure 1) suspend the neuron-scolopale-cap cell complex from the epidermis. Both of these cells usually lengthen into thin cables that are attached to the epidermis. Ligament cells seem to be absent in many chordotonal organs (e.g., Johnston's organ, ventral larval chordotonal organs in *Drosophila*), and, also, attachment cells have not been positively identified in all cases.

A structure found uniquely in chordotonal organs is the scolopale, a circular array of thick cytoskeletal bundles that form in the cytoplasm of the scolopale cell. As the interior of the scolopale cell cavitates to receive the sensory dendrite, densities ("rods" formed by closely packed actin and tubulin filaments) form at regular intervals around the inner cavity (Figure 17g). Towards the later stages, the cell membrane bordering the inner cavity of the scolopale cell recedes peripherally, so that the scolopale rods come to lie inside the cavity, surrounding the outer dendritic segment (see the TEM of the mature chordotonal organ shown in Figure 4). Both the scolopale and the dendritic cap formed by the scolopale cell around the tip of the outer dendritic segment are thought to play an essential role in mechanotransduction.

1.11.4.2.2. Chordotonal organ in *Periplaneta* The morphogenesis of a chordotonal organ in *Periplaneta*, investigated by Bloechl and Selzer (1988), varies in several early aspects from that reported for *Drosophila*. Some of these differences are informative in regard to the homologization between

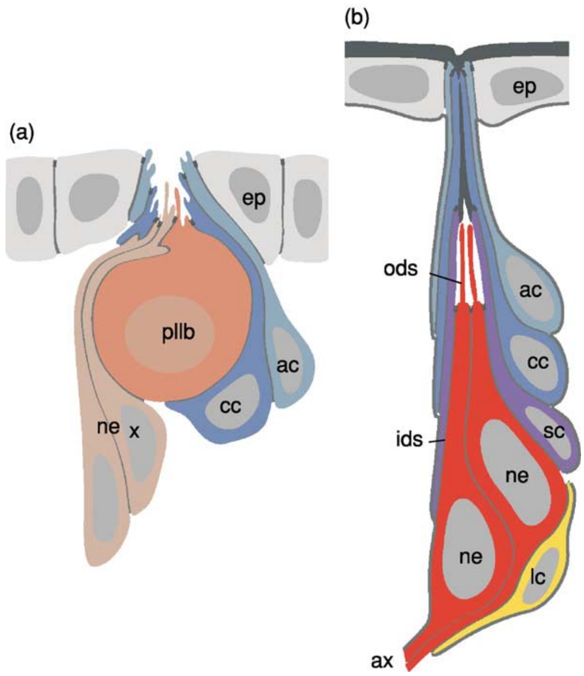

Figure 18 Development of the chordotonal organ in *Periplaneta*. Schematic longitudinal sections of nascent chordotonal organ at early (a) and late (b) embryonic stages. In a, the outer accessory cells (ac, attachment cell; cc, cap cell) are postmitotic, whereas the pIIb progenitor of neurons and scolopale cell is just dividing. All three of these cells are in contact with the apical surface. Two transient neurons (ne_x) which will later undergo apoptotic cell death are also visible at this stage. At the late stage depicted in panel b, all cells have reached their final disposition. Note that the outer accessory cells are still in contact with the apical epidermal surface. (Reproduced with permission Bloechl, R., Selzer, R., **1988**. Embryogenesis of the connective chordotonal organ in the pedicel of the American cockroach: cell lineage and morphological differentiation. *Cell Tissue Res. 252*, 669–678; © Springer–Verlag.)

the cells of a chordotonal organ and external sensilla. In *Periplaneta*, the dividing SOP daughter cells remain integrated into the epidermis. Even in the mature organ, the two outer accessory cells are in contact with the apical surface via thin cytoplasmic necks, whereby the neck of the outer one (corresponding to the attachment cell in *Drosophila*) surrounds mesaxon-like the neck of the inner one (the cap cell; Figure 18). This arrangement of the outer accessory cells in *Periplaneta* supports the homology of the attachment cell with the tormogen cell of an external sensillum, and of the cap cell with the trichogen cell.

1.11.4.2.3. Molecular aspects of chordotonal organ differentiation Given the strong similarity between cells forming external sensilla and chordotonal organs, it comes as no surprise that the majority of proteins encountered above in discussing external sensillum differentiation are involved in quite similar ways in chordotonal organ differentiation. This holds particularly true for proteins involved in the development of the sensory dendrites (e.g., Rfx, NompA, NompB; Dubruille *et al*., 2002; Caldwell and Eberl, 2002). A few genes that seem to be required exclusively in dendrite formation in chordotonal organs and not in external sensilla are *beethoven* (*btv*; a putative cadherin) and *tilB/smetana* (*smet*; Eberl *et al*., 2000; protein as yet unknown). This suggests that significant differences exist at the molecular level between chordotonal organs and external sensilla in regard to the way in which sensory dendrites form. These differences are reflected in a number of structural details that set chordotonal dendrites apart from external sensillum dendrites (see section above).

1.11.4.3. Differentiation of Type II Multidendritic Sensilla

Multidendritic (MD) sensory neurons develop from the same SOP lineages that also give rise to external sensilla. Following the division of pIIb, these cells obtain a subepidermal position. Typically, MD neurons do not become associated with non-neuronal accessory cells, but differentiate at the positions where they were born as isolated, scattered cells, attached to the basal surface of the epidermis (Bodmer and Jan, 1987; Bodmer *et al*., 1989; Brewster and Bodmer, 1995; Orgogozo *et al*., 2001; Grueber *et al*., 2002; Lai and Orgogozo, 2004). Some MD neurons are associated with internal structures, including tracheal branches, muscle fibers, or peripheral nerves (see **Chapters 2.1**, **2.3**, **2.4**, and **2.7**).

MD neuron differentiation has been followed in *Drosophila* (Grueber *et al*., 2002; Sugimura *et al*., 2003), and numerous genes involved in their morphogenesis have been identified in genetic screens (Gao *et al*., 1999, 2000). As described for other insect groups (Grueber *et al*., 2001; and discussed earlier), *Drosophila* possesses four classes of MD neurons which differ in dendritic complexity and physiological properties (see **Figure 5**). Differentiation begins in the late embryo when each neuron extends two to five primary dendrites and an axon. The first dendrites are directed dorsally; they are followed by lateral dendrites extending anteriorly and posteriorly (**Figure 19a1–4**). During the larval period, which is characterized by an enormous increase in body size, the complexity of the dendritic arbors increases. This is achieved by successive bifurcations of dendrites at their tip, as well as by outgrowth of higher order branches along the entire length of the primary dendrites (**Figure 19a5**).

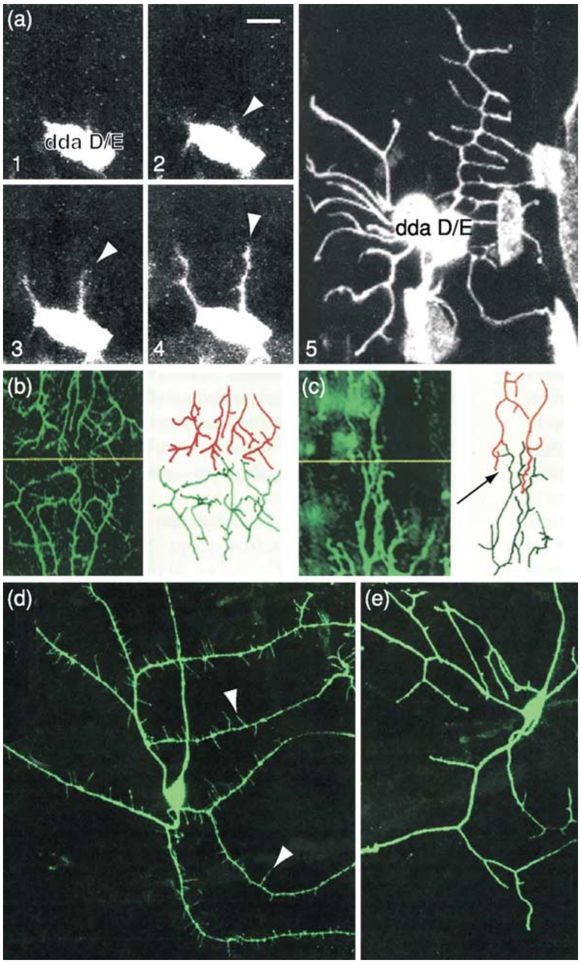

Figure 19 Development of multidendritic neurons. (a) Images of labeled ddaD/E neurons in the late embryo (a1–4) and larva (5). Note the fast outgrowth of vertical dendrites (arrowheads) in the embryo; secondary branching takes place in the larva (5). (b) Dendrites of wild-type dorsal MD neurons (labeled green) from both sides meet at the dorsal midline (yellow line) but do not overlap. The drawing shows MD dendrites of a right hemisegment in red, and of the corresponding left hemisegment in green. In *flamingo* mutant embryos (c), overlap of the dorsal MD dendrites are frequent (arrow). (d) Labeled MD neuron ddaA in a wild-type *Drosophila* larva. This neuron belongs to the γ class of MD neurons (see **Figure 5**), characterized by a wide dendritic arbor and multiple secondary branches (arrowheads). Loss of *cut* (e) causes a reduction in dendrite size and loss of secondary branches. Scalebar = 5 μm (a–e). ((a): Reproduced with permission from sugimura, K., Yamamoto, M., Niwa, R., Satoh, D., Goto, S., **2003**. (d, e): Reprinted with permission from Grueber, W.B., Jan, L.Y., Jan, Y.N., **2003**. Different levels of the homeodomain protein Cut regulate distinct dendrite branching patterns of *Drosophila* multidendritic neurons. *Cell 112*, 805–818; © Elsevier.)

Mature MD neurons of a given class have dendritic arbors that completely tile the bodywall. In *Drosophila*, a single MD neuron spans the entire antero-posterior length of the segment it is located in, but stops abruptly at the segment boundary. Dendritic arbors of dorsally-located MD neurons reach the dorsal midline, but do not cross over it, and therefore avoid any overlap with the dendrites of their contralateral counterpart (**Figure 19b**). This suggests that repulsive interactions exist between adjacent neurons. Such interactions could indeed be shown by ablating individual MD neurons, and observing that dendrites of the serial homologs of these cells in adjacent segments spread into the territory vacated by the ablated cell. An adhesion molecule of the cadherin family, Flamingo (Fmi), has been shown to be involved in restricting dendritic growth of MD neurons (Gao *et al*., 2000). Lack of Fmi causes exuberant dorsal growth and overlap of dendritic arbors of homologous MD neurons (**Figure 19c**).

Another regulator of dendritic arborization is the homeodomain protein Cut (Ct) that was discussed in the context of SOP fate specification (see above). Cut is expressed in SOPs of external sensilla and MD neurons, in which it remains detectable after differentiation has set in. The level of Cut expression is correlated with dendritic complexity, in that MD neurons with larger and more highly branched dendritic arbors express more Cut than MD neurons with simpler dendrites (Grueber *et al*., 2003). Experimental studies confirmed the hypothesis that Cut is causally related to dendrite formation: removal of this protein in individual dendritic arbor neurons caused a dramatic drop in the complexity of the corresponding dendrites (**Figure 19d** and **e**).

1.11.4.4. Axonal Arborization of Sensory Neurons

Axons of sensory neurons project towards the CNS where they arborize in the neuropil. A great wealth of information exists on the details of sensory axonal arborization patterns and the neuronal circuits in which they are integrated (see **Chapters 1.10** and **2.4**). Presenting these data in adequate detail would exceed the scope of this chapter, and only a brief survey of important general aspects of sensory projections will be given here.

As a general rule, sensory axons project to the neuromere of the segment to which the corresponding sensilla belong. Bristles of the fly wing project to the mesothoracic neuromere; taste sensilla on the labium project to the subesophageal ganglion (that contains the labial neuromere), and olfactory neurons of the antenna to the antennal neuromere

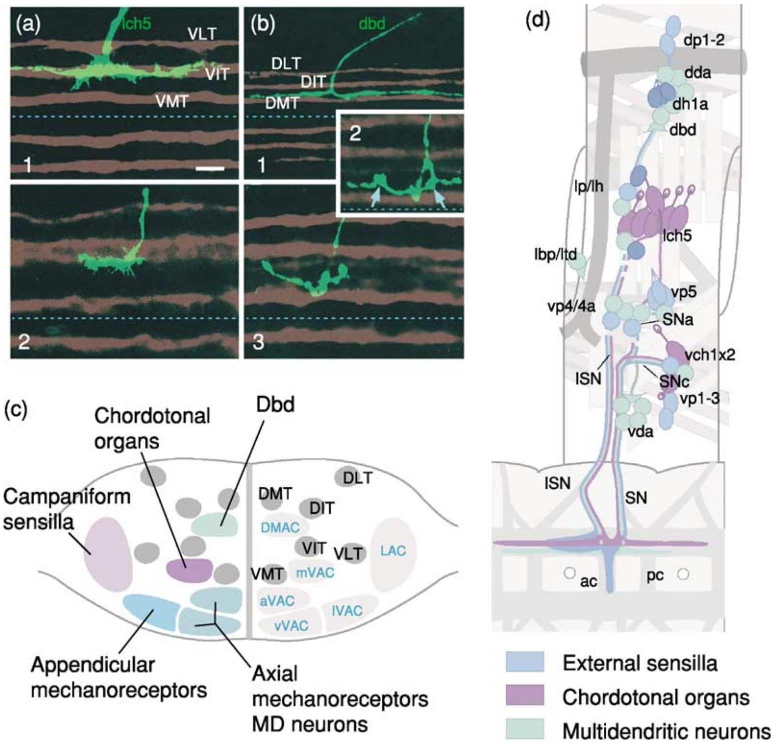

Figure 20 Sensory projections in the central nervous system (CNS). (a, b) Dorsal view of *Drosophila* late embryonic ventral nerve cord where principal longitudinal tracts are labeled with anti-Fasciclin II antibody (brown; DIT, dorso-intermediate tract; DLT, dorso-lateral tract; DMT, dorso-medial tract; VIT, ventro-intermediate tract; VLT, ventro-lateral tract; VMT, ventro-medial tract). Blue dotted line indicates midline of the CNS. In (a), the sensory neuron of the lateral pentascolopidial chordotonal organ (lch5; green) was filled with Lucifer yellow to show the axonal termination close to the VIT tract. (a1) and (a2) represent two different stages (stages 16 and 17, respectively) in development. Note that the lch5 termination relative to the VIT tract remains unchanged, whereas the longitudinal extent of projection retracts with age. In (b1–3) the dbd neuron was labeled. Terminal arborizations of this cell are found more dorsally and medially, close to the DMT tract. (c) Schematic cross-section of a generalized insect ventral nerve cord in which tracts (dark gray, black lettering) and sensory neuropils (light gray; blue lettering) are identified on the right side. On the left side site, sensory modalities are correlated with specific sensory neuropils. (d) Schematic drawing of an abdominal (a1–7) hemisegment in which sensilla and muscle fibers are depicted. The dorsal midline is at the top, the ventral midline at the bottom; anterior is to the left. Colored profiles show sensory neurons belonging to external sensilla (blue), chordotonal organs (violet), and multidendritic neurons (green). Somatic muscle fibers are shown in gray. The axonal projection of different classes of sensilla through the intersegmental nerve (ISN) and the segmental nerve (SN) and the site of termination in the ventral nerve cord are illustrated. Scalebar = 10 μm. ((a, b): Reprinted with permission from Zlatic, M., Landgraf, M., Bate, M., **2003**. (d) Adapted from Campos-Ortega, J.A., Hartenstein, V., **1997**. The Embryonic Development of *Drosophila melanogaster*, 2nd edn. Springer, Berlin.)

(called the deuterocerebrum). One can go one step further in stating that the terminal arbors of most sensory neurons are restricted to the segment to which these neurons belong (**Figure 20b**). There are, however, notable exceptions such as the axons of scolopidium #4 of the *Drosophila* lch5 chordotonal, which ascend along the entire length of the ventral nerve cord (Schrader and Merritt, 2000).

Within a neuromere, sensory axonal arborizations are restricted to certain sensory modality-specific domains. These domains have been defined for several insect species (to name but a few studies: Murphey *et al*., 1985, 1989; Pflüger *et al*., 1988; Newland, 1991; Merritt and Whitington, 1995; Schrader and Merritt, 2000; Zlatic *et al*., 2003). To subdivide the neuropil, the main bundles of longitudinal axons serve as useful landmarks. There exist three rather evenly spaced sets of these bundles, a medial, an intermediate, and a lateral set (**Figure 20a–c**; Pflüger *et al*., 1988; Nassif *et al*., 2003; Zlatic *et al*., 2003). Both medial and lateral sets comprise a dorsal and a ventral bundle (DMT and VMT; DLT and VLT, respectively). The intermediate set contains a dorsal bundle (DIT) and several

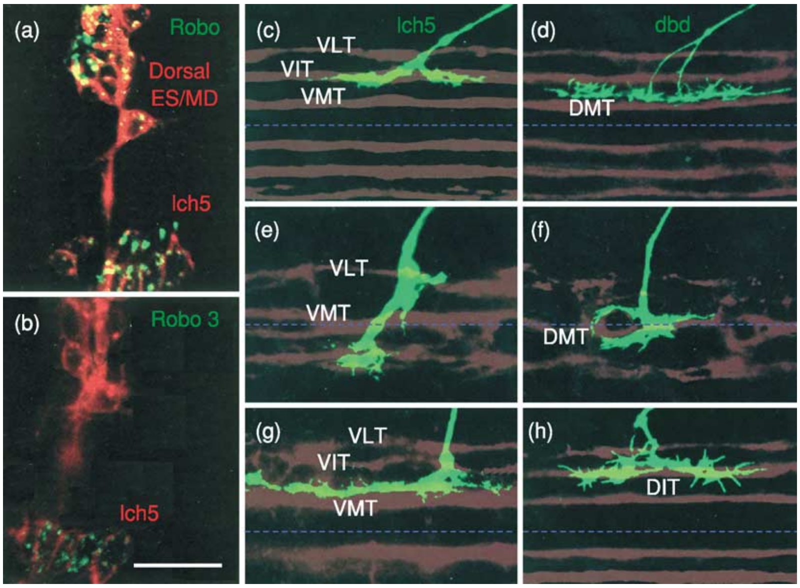

Figure 21 The role of Robo receptors in controlling sensory axonal projections. (a) Robo (green) is expressed in all *Drosophila* embryonic sensory neurons, including the multidenrtitic neurons (MD) and external sensilla (ES) of the dorsal group, and lateral chordotonal organs (lch5). (b) Expression of Robo 3 is restricted to chordotonal organs. (c, d) Termination of axon of lch5 (c) on VIT tract and axon of dbd stretch receptor (dbd) on DMT (d) in wild-type *Drosophila* ventral nerve cord. Blue dotted line indicates midline. (e, f) Mutation of Robo results in abnormal central tracts and midline crossings of chordotonal axons (e) and dbd axons (f). (g) Loss of Robo 3 causes chordotonal axon to project to a more medial position near the VMT. (h) Ectopic expression of Robo 3 in dbd forces dbd axonal termination into a more lateral position near the DIT. Scale bar = 10 μm (a–h). (Reprinted with permission from Zlatic, M., Landgraf, M., Bate, M., **2003**. Genetic specification of axonal arbors: atonal regulates robo3 to position terminal branches in the *Drosophila* nervous system. *Neuron 37*, 41–51; © Elsevier.)

small bundles (VIT1-3) extending along the center of the neuropil. The domain that receives sensory axons is located predominantly in the ventral half of the neuropil. Within the sensory neuropil, axons of tactile receptors occupy a domain ventral of that of proprioceptors (chordotonal organs, MD stretch receptors; Pflüger *et al*., 1988; Schrader and Merritt, 2000; Zlatic *et al*., 2003; **Figure 20c**). Tactile hairs (trichoid sensilla) and multidendritic neurons, located on the trunk, project to a ventromedial domain surrounding the VMT bundle (**Figure 20c** and **d**); trichoid sensilla on the appendages project more laterally to a neuropil domain ventral and lateral of VLT. In several instances, a pronounced somatotopic ordering of sensory projections has been identified. For example, projections of trichoid sensilla on the dorsal trunk terminate dorsally of those from ventral sensilla (Pflüger *et al*., 1988). Terminal arbors of chordotonal organs are found dorsally of tactile projections, surrounding the VIT bundles (**Figure 20a** and **c**). Some stretch receptors have terminal arbors that are even more dorsal. For example, the *Drosophila* dbd stretch receptor terminates around the DMT bundle (**Figure 20b** and **c**); external proprioceptors, such as the campaniform sensilla and hairplates located on the legs, project to a dorsolateral domain within the neuropil.

Recent findings have provided a first insight into the molecular mechanisms that control the pattern of sensory projections in the CNS. A pivotal element of this mechanism is the extracellular signal Slit, which emanates from the midline cells of the CNS and forms a medio-lateral gradient. Axons of many neurons, including the central inter- and motoneurons and peripheral sensory neurons, express receptors for Slit (Rajagopalan *et al*., 2000; Simpson *et al*., 2000; Guthrie, 2001; Wong *et al*., 2002). Three different receptors, encoded by the *roundabout* genes (*robo*, *robo 2*, *robo 3*) and having different affinities for Slit have been identified. Slit acts as a repellant, so that axons, which express Robo and thereby become sensitive to Slit, stay away from the midline (i.e., do not cross) and form longitudinal projections instead. Furthermore, the expression of Robo receptors with different affinities for Slit determines the distance between an axon and the midline. Axons expressing Robo 3 (high affinity) keep at a greater distance from the midline than axons which only have Robo.

The correlation between Robo type expression and projection pattern has been experimentally

addressed in the *Drosophila* sensory axons (Zlatic *et al.*, 2003). Robo is expressed by all sensory neurons, and is responsible for maintaining sensory axons ipsilaterally. Loss of the gene encoding Robo causes many sensory axons to cross the midline and form bilateral projections (Figure 21e and f). Chordotonal neurons express Robo 3, beside Robo 4, and it is this high-affinity receptor for Slit that maintains the position of chordotonal sensory axons at a position more lateral than that of axons of external sensilla and MD sensilla. Mutations in Robo 3 cause chordotonal axons to terminate at a medial position (Figure 21g); vice versa, expressing Robo 3 in MD neurons forces the axons of these cells into a more lateral position (Figure 21h).

One might assume that the type of Robo receptor expressed by a sensory neuron is ultimately under the control of the SOP identity gene that is responsible for the overall morphology of the sensillum which the neuron is part of. Such control has been demonstrated to exist for Robo 3, expressed in chordotonal neurons as a target of the proneural/SOP identity gene *atonal* (Zlatic *et al.*, 2003). Expressing *atonal* in MD neurons turns on Robo 3 in these cells and changes their sensory projection to that normally seen for chordotonal neurons.

1.11.5. Phylogenetic Aspects of Sensillum Structure and Development

1.11.5.1. Coelenterates and "Lower" Bilateria

Sensory structures integrated into the epidermal covering of the body can be found in all invertebrate phyla from coelenterates onward. In coelenterates and "lower" protostomes (e.g., flatworms), such structures comprise single or clustered sensory neurons whose dendrite is a modified cilium (Chia and Koss, 1979; Wright, 1992; Kass-Simon and Hufnagel, 1992; Figure 22b and c). In evolutionary terms, such ciliated peripheral neurons can be regarded as modified epidermal cells, whom they resemble closely in their ultrastuctural appearance. Thus, the epidermis of coelenterates and flatworms consists of an epithelial layer of ciliated cells, and coordinated ciliary beating is the mechanism by which coeleneterates and flatworms move. Each epidermal cell produces one (in coelenterates) or multiple (in flatworms) cilia, which are surrounded by microvilli (Figure 22a). A similar morphology is seen in sensory neurons of lower invertebrates. However, unlike those of epidermal cells, cell bodies of sensory neurons are often sunken beneath the level of the epidermis or can even reside within the CNS. Furthemore, the ciliary dendrites can take on various shapes in accordance with their mechano- or chemoreceptive function (Figure 22d). In most sensory neurons, microvilli remain inconspicuous, although neurons with large microvillar processes resembling the stereocilia of hair cells in vertebrates (see below) have been observed (Figure 22d). Accessory cells, such as the trichogen or tormogen cell of arthropods, are rare or absent in lower invertebrates.

The special senses of lower invertebrates comprise simple eyes and statocysts (gravity receptors). Eyes

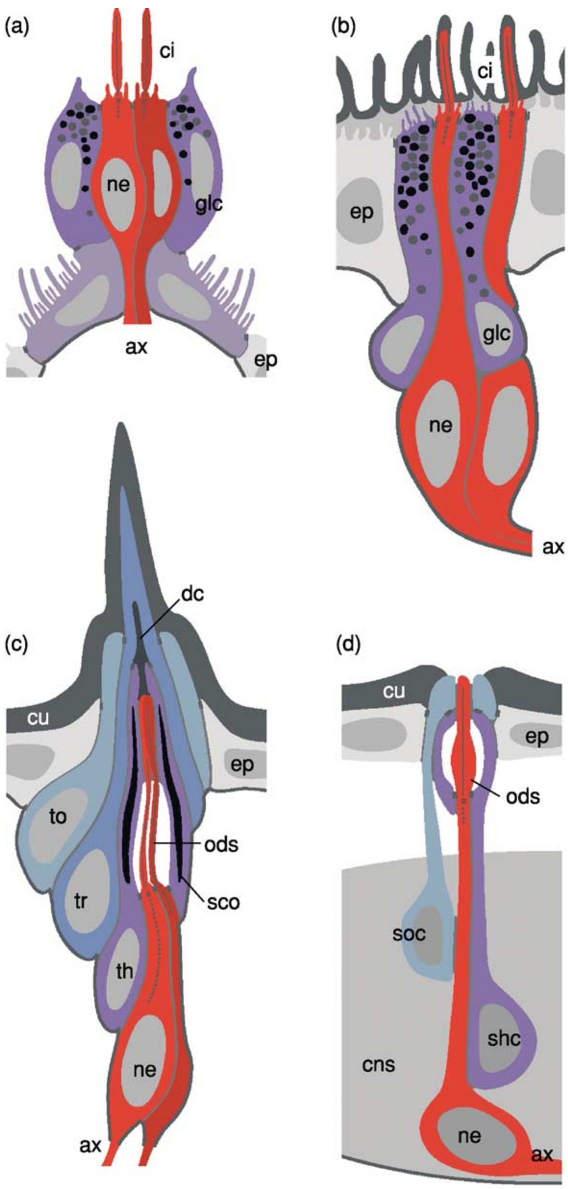

Figure 23 Sensilla in ''higher'' protostomes. Ciliated sensory neurons (ne) have aquired specialized epidermal support cells (ep) with possible glandular function (glc) in mollusks (a) and annelids (b). Crustacean external sensilla (c) closely resemble insect sensilla. As shown in this diagram, neurons (ne) and thecogen cells (th) show attributes seen only in chordotonal organs in insects (sco, scolopale). (d) The nematode sensillum typically contains ciliated neuron (ne) and two accessory cells, a socket cell (soc) and sheath cell (shc). Cell bodies of all sensillum cells are contained within the central nervous system (cns). ax, axon; ci, cilium; cu, cuticle; dc, dendritic cap; ods, outer dendritic segment (modified cilium); sco, scolopale; to, tormogen cell; tr, trichogen cell. consist of clusters of ciliated cells in which either the cilium (ciliary photoreceptors) or the microvilli (rhabdomeric photoreceptors) are grossly enlarged to carry the photopigment. A statocyst is formed by a fluid-filled vesicle lined by an epithelium. The epithelium produces the statolith, a minuscule sphere of calcified extracellular material that moves around in the statocyst as the animal changes its position relative to gravitational pull. The epithelial lining of the statocyst contains sensory neurons. Movement of the statolith will bend the cilia of these neurons and thereby elicit a receptor potential.

1.11.5.2. "Higher" Protostomes: Annelids, Mollusks, Nematodes, Arthropods

The repertoire of sensory structures characterized for annelids and mollusks is similar to that seen in lower invertebrates (Dorsett, 1976; Bullock *et al.*, 1977). Bipolar sensory neurons with a ciliary dendrite occur singly or in clusters integrated in the epidermis of the body wall and feeding structures. Accessory cells are absent in most cases, but have been described for both mollusks and annelids, where ciliated sensory neurons are surrounded by specialized cells filled with secretory granules (**Figure 23a and b**). It is unknown whether sensory neurons, and such accessory cells form a lineage derived from a single SOP-like progenitor cell. Subepidermal sensory neurons, which are likely to serve as stretch receptors have been identified in annelids and cephalopods. These cells are multipolar, similar to insect MD neurons, and stretch out at the basal surface of the epidermis and around muscles. In polychaete worms, similarly shaped cells send branched dendrites to the internal processes of the large setae and react to deflections of the setae, not unlike the mechanosensitive trichoid sensilla in insects. Again, it is not known whether the setae-forming cell(s) and sensory neurons form part of a lineage born from single progenitor cells.

Sensilla, closely resembling those described for insects in this chapter, exist in all arthropod classes (Hallberg and Hansson, 1999). External sensilla with lineages comprising sensory neurons and inner and outer accessory cells forming sheaths around the dendrite were found in crustaceans (**Figure 23c**), spiders, and myriapods. Similarly, internal MD neurons have been found in all classes. Chordotonal organs, alternatively, seem to be present only in crustaceans and insects, which reinforces the notion that these two classes are more closely related and have further evolved from the arthropod ancestor. Comparing the morphology of external sensilla and chordotonal organs in crustaceans and insects provides several clues to the evolution of chordotonal organs. Thus, whereas in insects the

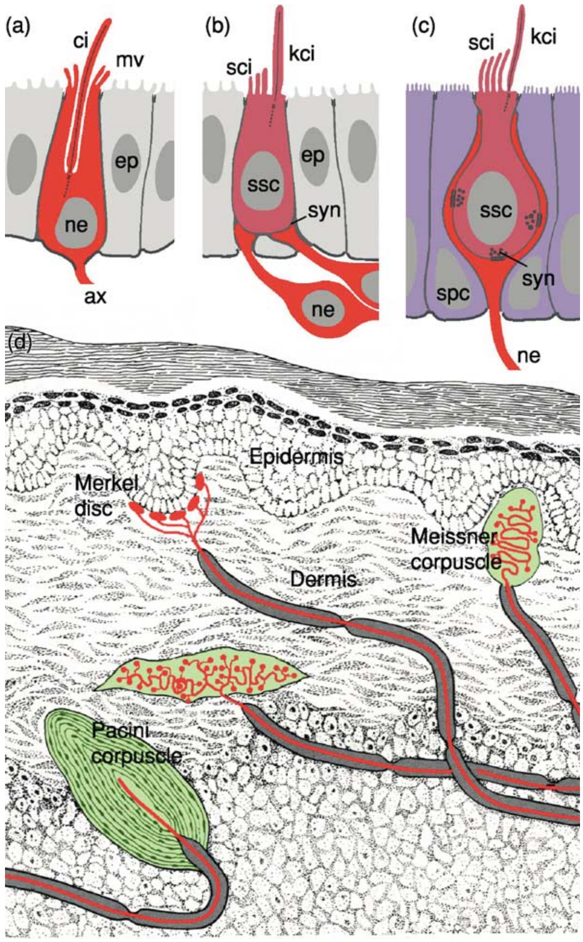

Figure 24 Sensilla in deuterostomes. (a) Primary ciliated sensory neuron (ne) in ascidian epidermis. (b) Secondary sensory cell (hair cell; ssc) in lateral line of fish, forming synaptic contact (syn) with bipolar neurons (ne). (c) Hair cell of vertebrate ear. Hair cells have apical specializations derived from microvilli (stereocilia, sci) and from cilia (kinocilia, kci). In the vertebrate inner ear, hair cells are surrounded by specialized support cells (spc). (d) Mechanoreceptors in vertebrates (green) are located in the deep layers of the skin (dermis) and develop from mesodermal cells contacted by sensory dendrites (red) of neurons located in dorsal root ganglia. ax, axon; ci, cilium; ep, epidermal cell; mv, microvillus. Review of Neuroscience. Macmillan Publishing, New York.)

two types of sensilla form discrete classes with several characteristic differences, this is not the case in crustacea. Here, many external sensilla with external (apical) processes possess a scolopale which is formed in the thecogen cell (Kouyama and Shimozawa, 1982; Merritt, 1997; **Figure 23c**). Vice versa, chordotonal organs of crustacea frequently possess external cuticular specializations. As discussed above, even in primitive insects the cap cells and attachment cells of chordotonal organs have processes inserted into the epidermis. From such findings, a picture emerges according to which chordotonal organs are derived from external sensilla, as in, for example, campaniform sensilla, which also serve as stretch receptors (Moulins, 1976; Merritt, 1997). Primarily, the outer accessory cells are an integral part of the epidermis and form specialized cuticle structures. The thecogen produces a dendritic cap, as well as a scolopale. Secondarily, the organ shifts underneath the epidermis, and the outer accessory cells no longer form cuticular specializations; this would bring the chordotonal organ to the level we find in cases like that described in Section 1.11.4.2.2 for *Periplaneta*. Finally, outer accessory cells move out of the epidermis altogether, producing the most "evolved" type of chordotonal organs prevalent in Diptera.

Nematodes have chemo- and mechanoreceptive sensilla composed of bipolar sensory neurons and two accessory cells called socket cell and sheath cell (**Figure 23d**; Ward, 1975; Wright, 1992). The cell bodies of neurons and accessory cells are internalized and form part of the CNS. However, as decribed for arthropods, the accessory cells form mesaxonal sheaths around the dendrite. Furthermore, as in arthropods, the ciliary outer dendritic segment is enclosed in a receptor lymph space formed by the sheath cell.

1.11.5.3. Sensilla in the Deuterostome Lineage

Peripherally located primary neurons with ciliated sensory dendrites can be found as integral part of the epidermis in all deuterostomes except vertebrates (**Figure 24a**). As in protostomes, the cell bodies of the sensory neurons are typically sunken beneath the level of the epidermis (Dorsett, 1976; Bone and Ryan, 1978). Specialized accessory cells may be present, but no lineage studies investigating the origin of sensory neurons and their relationship to accessory cells have been performed. Arrays of ciliated mechanosensitive cells which have lost their axon and are associated with secondary sensory neurons have been recently identified in the urochordate *Ciona*. These cells may represent the evolutionary ancestor of the lateral line system and inner ear of vertebrates.

With the evolution of vertebrates a dramatic change in the structure of sensory organs, in particular those of the trunk region, has taken place. Ciliated primary sensory neurons have all but disappeared from the periphery. In their stead, mesodermally-derived sensory organs located in the deep layers of the skin act as mechanoreceptors (**Figure 24d**). These structures, including among others the Pacini corpuscles and Merkel's discs, react to stretching and compression of the overlying skin. They are

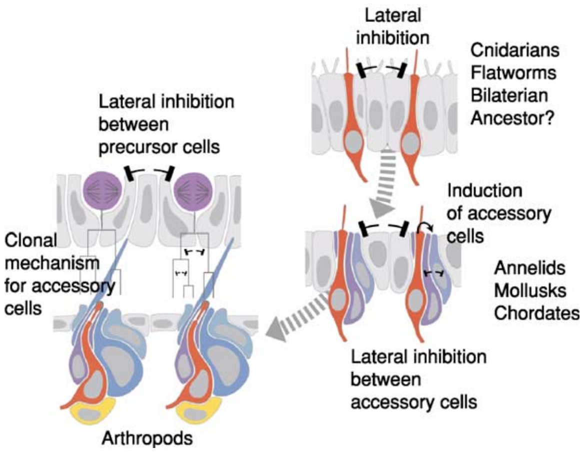

Figure 25 Phylogeny of sensilla. Three stages are proposed: naked ciliated sensory neurons; simple sensilla where sensory neurons recruit adjacent epidermal cells into specialized accessory cells; and clonally derived sensilla in which cell fates of neurons and accessory cells are specified by intrinsic determinants distributed during the asymmetric divisions of SOPs.

innervated by the dendrites of secondary sensory neurons whose cell bodies are far away from the sensory structures themselves, residing in the dorsal root ganglia near the spinal cord. Other classes of sensory neurons with "free ending" dendrites exist. Among these are neurons sensitive to temperature and tissue damage (pain). One structural correlate to the disappearance of invertebrate-type sensilla from the body wall of vertebrate is the thick protective "armor" (scales, keratin layer, hair, feathers) produced by the multilayered skin. These specializations would render the mechanoreceptive function of microscopic sensilla ineffective.

Ciliated sensory neurons with chemo- and mechanosensitive function do still exist in the vertebrate head. They comprise primary sensory neurons integrated into the mucous membranes of the nose, and the hair cells of the inner ear/lateral line system (Figure 24c). Olfactory receptors consist of primary sensory neurons with branched ciliary dendrites, surrounded by glandular support cells. The inner ear consists of a complex of liquid filled vesicles. The vesicles are lined by an epithelium that consists of sensory hair cells surrounded by support cells. The "hairs" of a hair cell consist of stereocilia, grossly enlarged microvilli filled with bundles of actin. Hair cells do not themselves produce an axon. They are innervated by the dendrites of secondary neurons whose cell bodies are clustered in the vicinity of the inner ear (Figure 24c). Movement of the liquid, induced by sudden changes of the position of the body relative to gravitational pull, or, in the case of the ear, by vibration of the tympanal membrane, leads to deflection of the stereocilia and elicits a receptor potential in the hair cells.

1.11.5.4. Conclusion: Evolution of Sensilla in the Metazoa

There is little reason to doubt that at the level of single cells (rather than complex organs) the sensory cells of the vertebrate head, which form part of the nose, inner ear, and eye, are homologous with invertebrate sensory neurons carrying out similar functions. Homology implies that the common ancestor, from which present day vertebrates and the various invertebrate taxa are derived, already possessed the structure stated to be homologous. Since even coelenterates (which branched off the animal tree before the bilaterian ancestor) possess ciliated mechano- and chemosensory neurons, it is safe to assume that the bilaterian ancestor had these cell types as well (Figure 25). Furthermore, it is reasonable to think that in the lines of ancestors leading up to the extant taxa, these cell types were continuously present. All extant taxa possess these cell types, and it is hard to envision ecological scenarios which would favor the disappearance of sensory cells that inform the organism about the chemical and mechanical aspects of its environment.

Molecular evidence supports the close phylogenetic relationship between certain sensory systems in all animals. Thus, the nasal mucosa and inner ear are derived from neurectodermal placodes (nasal placode, otic placode) that invaginate in the wake of neurulation, and give rise to the sensory receptors and support cells that make up the mature structure. Transcription factors of the bHLH family act as regulatory genes required for the fate of sensory neurons (Guillemot *et al.*, 1993; Perez *et al.*, 1999). For example, the vertebrate homolog of the *Drosophila achaete* gene is expressed and required in the olfactory neurons of the nasal mucosa, as well as the dorsal root ganglion cells innervating mechanoreceptory organs of the skin (Guillemot *et al.*, 1993). Recent findings further show how lateral inhibition mediated by N/Dl signaling underlies the separation of sensory cells and support cells in the otic placode (Eddison *et al.*, 2000). Removing the function of this pathway at the critical time results in an excess of support cells and lack of sensory neurons/hair cells, similar to the situation in *Drosophila*, where N activation is repeatedly required in those branches of the SOP lineage that lead to accessory cells.

One can thus envisage an evolutionary scenario that started out with an organism containing "naked" sensory neurons scattered over the

bodywall, resembling the situation presented by present day coelenterates or flatworms (**Figure 25**). It is possible that lateral inhibition involving the N pathway took part in controlling the number and spacing of sensory neurons. The next step was taken with the formation of accessory cells, specialized epidermal cells which protect the neuron and aid in presenting and/or transducing the stimulus. Such accessory cells are variably present in sensilla of "higher" animals. Initially, they might have been induced by signals sent out by the sensory neurons. Signaling pathways, including the EGFR pathway, still play a prominent role in the recruitment of accessory cells in the *Drosophila* compound eye, as well as the induction of SOPs in many modular sensory organs such as chordotonal organs and dense arrays of external sensilla (see section above). The N signaling mechanism was recruited into the specification of accessory cells also. Initially responsible for the pattern of sensory neurons, this pathway also controlled the number and arrangement of accessory cells surrounding each sensory neuron. Finally, in arthropod sensilla and selected chordate sensory organs, a clonal mechanism became an essential factor that was able to guarantee a precise pattern of sensillum cells.

Some recent molecular results have prompted evolutionary speculations on homologies between vertebrate and invertebrate (*Drosophila*) sensory organs that appear unrealistic in the light of existing data. An example is the comparison of the inner ear hair cells in vertebrates and chordotonal organs in *Drosophila*. Starting the debate was the finding that one of the vertebrate homologs of *atonal*, the proneural gene required for *Drosophila* chordotonal organs, some of which serve auditory functions, is also expressed and required in hair cells/sensory neurons of the inner ear (Bermingham *et al*., 1999; Chen *et al*., 2002). The question was raised by subsequent authors, prompting the question of whether specific homologies exist between inner ear and insect chordotonal organs. This question can be answered in the negative with reasonable certainty, given what we know about the structure and function of chordotonal organs and their occurrence among animals. As presented above, chordotonal organs are relative "late-comers" in evolution, lacking in myriapods and chelicerates and all non-arthropods. The recruitment of chordotonal organs into the auditory function most likely occurred even later than the origin of these organs themselves, given that most chordotonal organs are stretch receptors associated with the trunk or joints of the appendages. Thus, it is extremely unlikely that the bilaterian ancestor possessed highly specialized sensory structures resembling chordotonal organs. Alternatively, one might speculate that there exists among the "naked" bipolar sensory neurons with mechanoreceptive properties (which one finds in all bilateria) a specialized class of cells which expressed Atonal, and which became repeatedly recruited into more complex sensory organs which sensed vibration and sound. This would explain the finding that auditory organs which, as multicellular organs, evolved convergently, still express homologous genetic pathways.

Appendix List of genes and gene products discussed in this chapter

achaete-scute complex (AS-C)		gene complex including *ac, sc, l'sc*
achaete (ac)	bHLH TF	proneural gene
amos (amos)	bHLH TF	proneural gene
atonal (ato)	membrane protein (signal)	neurogenic gene
BarH1, BarH2	homeodomain TF	sensillum fate determinant
bazooka (baz)	cytoplasmic protein	asymmetric mitosis
beethoven	details unknown	
crinkled (ck)	myosin VII	microfilament function
cut (ct)	Homeodomain TF	SOP identity gene
decapentaplegic (dpp)	secreted TGF-like signal	morphogen
Delta (Dl)	membrane-bound signal	lateral inhibition
dishevelled (dsh)	cytoplasmic protein	planar cell polarity
elav	RNA binding protein	neural fate determinant
Enhancer of split [E(spl)]	HLH TF	neurogenic gene
flamingo (fmi)	cadherin-adhesion molecule	planar cell polarity
forked (f)	actin binding protein	microfilament bundling
frizzled (fz)	membrane receptor	planar cell polarity
glial cells missing (gcm)	TF	sensillum fate determinant
groucho (gro)	TF	modulates N signaling
hairless (H)	TF	inhibitor of Notch

Continued

Appendix Continued

hamlet (ham)	TF	sensillum fate determinant
hedgehog (hh)	secreted signal	morphogen
inscuteable (insc)	cytoplasmic protein	asymmetric mitosis
iroquois (iro)	homeodomain TF	coordinate gene
lethal of scute (*l'sc*)	HLH TF	proneural gene
no mechanoreceptor. potential A (nompA)	cytoplasmic protein	cilium formation
no mechanoreceptor. potential B (nompB)	membrane protein	dendritic cap
Notch (N)	membrane receptor	neurogenic gene
numb (numb)	cytoplasmic protein	inhibitor of Notch
pannier (pnr)	GATA TF	coordinate gene
phyllopod (phyl)	cytoplasmic protein	signal transducer in RAS pathway
pox-neuro (poxn)	paired box TF	SOP identity gene
prospero (pros)	TF	sensillum fate determinant
Drosophila rfx (Drfx)	TF	cilium formation
Drosophila rhoA (DrhoA)	GTPase	modulates microfilaments
roundabout (robo)	receptor	axonal pathfinding
scute (*sc*)	bHLH TF	proneural gene
shotgun (shg)	E-cadherin (DE-Cad)	adhesion, asymmetric cell division
singed (sn)	actin binding protein	microfilament bundling
Slit (Sli)	secreted signal	axonal pathfinding
sparkling/shaven (sv)	paired box TF	sensillum fate determinant
spitz (spi)	secreted TGFa-like signal	activates RAS pathway
Suppressor of Hairless (Su(H))	TF	inhibitor of Hairless
tilB/smetana (*smet*)	details unknown	
tramtrack (trk)	BTB/POZ TF	sensillum fate determinant
uncoordinated (unc)	cytoplasmic protein	axoneme formation
wingless (wg)	secreted signal	morphogen

TF = transcription factor.

1.12 The Development of the Olfactory System

G S X E Jefferis and L Luo, Stanford University,
Stanford, CA, USA

1.12.1. Introduction

1.12.1.1. Significance

Of all the sensory modalities, the olfactory system has historically been among the least studied in vertebrates. In contrast, there has been long-standing work in insects on its structure, development, and function. This stems in part from the recognition that olfaction is ethologically important for most insects, guiding them to food, mates, suitable oviposition sites, and so on. Besides this ethological interest, the development of the olfactory system should be of interest to developmental neurobiologists; olfaction is perhaps an unusual sense in which information enters the brain in a large number of parallel channels each distinct from one another. These channels, defined by the expression of different olfactory receptor molecules, serve as precise markers of neuronal identity. The olfactory system is therefore an excellent model for the formation of specific connections between identifiable components of neuronal networks. Furthermore, the vertebrate and insect olfactory systems show a common organizational logic, which suggests that insights gained with comparative facility in insects should be of interest to developmental neurobiologists at large. Finally, neurons and neuronal circuits in the olfactory system have proven excellent models of learning and memory, neuronal morphogenesis, developmental plasticity (neurite pruning during metamorphosis), and in some instances adult plasticity. All of these areas would benefit from an understanding of the underlying developmental mechanisms.

1.12.1.2. Scope of the Review

This review will emphasize the general principles of olfactory development in insects. *Drosophila melanogaster* will frequently be used as a model, reflecting in part the authors' own research interests and

the rapid progress occurring in our understanding of the developmental basis of this particular insect's sense of smell. This also reflects the practical limitations of space – a comprehensive summary of all that is known about the development of olfactory systems in all insects would occupy a volume rather than a chapter. Where there are clear gaps in our knowledge of *Drosophila*, detailed information will be drawn from other insects. In other cases, *Drosophila* findings are described in detail and comparisons and contrasts have been made with other insects, including moths and honeybee among holometabolous insects, and cockroaches and locusts among hemimetabolous insects.

In holometabolous insects, which undergo a complete metamorphosis and therefore form both a larval and an adult olfactory system, focus is made on the adult system. However, parts of the larval system persist through metamorphosis to the adult and even those structures that degenerate during metamorphosis may act as developmental cues during the formation of the adult structures. Although the development of the larval olfactory system is not described, its structure preparatory to a discussion of development of the adult olfactory system is reviewed.

Finally, this review will be written from a neurobiological perspective with an emphasis on the development of olfactory neuronal circuits over morphological development of olfactory structures.

1.12.1.3. Other Sources of Information

A valuable single source of information on the structure, function, and certain aspects of the development of the olfactory system is the volume *Insect Olfaction* (Hansson, 1999). In particular, there is an excellent review of the development of the antennal lobe, especially the glomeruli (Salecker and Malun, 1999). For the structure, function, and development of the mushroom body, a themed issue of the journal *Learning and Memory* (Mushroom Body Special Issue, 1998) is a valuable resource. However, there have been significant advances in certain areas since the publications of these sources. One point of great importance has been the identification of olfactory receptors in *Drosophila* through genome sequencing efforts. Since olfactory receptors define the channels of incoming olfactory information, they also serve as excellent markers for understanding the logic of wiring in this system. Keller and Vosshall (2003) is a good starting point for this work. Looking to functional analysis of the olfactory system, the application of optical imaging methods has allowed the parallel monitoring of a much greater fraction of the olfactory response (reviews: Galizia and Menzel, 2000; Korsching, 2002), although this new approach has yet to attain either the temporal resolution or sensitivity of traditional electrophysiology. Finally, significant advances have been made in the molecular and cellular basis of olfactory learning and memory, focusing on the mushroom body; Heisenberg (2003) provides a comprehensive and thoughtful review of this work.

1.12.2. Anatomy and Function

1.12.2.1. Olfaction: Logic and Function
